## VOID RATIO AND SHEAR STRENGTH OF

TWO COMPACTED CRUSHED STONES<sup>1</sup>

by

Fernando H. Tinoco, Richard L. Handy and James M. Hoover<sup>2</sup>

#### ABSTRACT

•

Triaxial compression tests of two crushed limestones of differing highway service records indicate a fundamental difference in their shear strength -- void ratio relationship. Analyses were based on stress parameters at minimum sample volume, i.e., before there was significant sample dilation due to shear. The better service record sample compacted to higher density, and had a high effective angle of internal friction and zero effective cohesion. The other sample compacted to lower density and had a lower friction angle, but gained significant stability from effective cohesion. Repeated loading-unloading cycles reduced the cohesion, apparently due to modification of the sample structure.

Extrapolations of the results to zero void ratio agree with sliding friction data reported on calcite, or with triaxial parameters reported on carbonate rocks.

 $^{\rm 1}$ A report of Project HR-99 sponsored by the Iowa Highway Research Board with funds from the Iowa State Highway Commission and the Bureau of Public Roads. Project 516-S of the Soil Research Laboratory, Engineering Experiment Station, Iowa State University, Contribution No. 66-6.

#### INTRODUCTION

Compacted crushed limestone has been in common use for many years as a base course for flexible pavements. In recent years the greatly increased traffic loads and intensities have resulted in mixed service records of this material. The present study is part of a larger research program being conducted at Iowa State University to discover and compare strength characteristics of several Iowa crushed stones with varying service records, and if possible to explain the performance differences and relate to compositional differences such as gradation or mineralogy.

•

#### BASIS OF THIS INVESTIGATION

The usual use of the Mohr stress circle in soils is to represent stress conditions at failure, with failure defined as the condition of the soil at the maximum deviator stress or maximum principal stress ratio. The Mohr failure envelope is the line representing the locus of points showing stress conditions on the failure plane. But since a Mohr circle also represents any two-dimensional stress condition of equilibrium, it can be used at any strain value before failure is reached. Thus the envelope formed by points of tangency to Mohr circles representing effective stresses for a given condition of the sample can be used to find the cohesion and angle of internal friction at that given condition.

In this study the selected condition is the minimum void ratio reached during the shear test. This condition was chosen because it

represents a time of maximum density, when stability and strength are presumed to be maximum. That is, although the Mohr stress parameters usually become larger as the test continues to failure, they then include energy used to increase the soil volume as grains move over one another to allow formation of continuous shear planes. When this happens, the soil structure is changed, and successive repetitions of loading were not expected to follow the same stress paths.

Another alternative might be to use the constant-volume condition, after the test has progressed to the point where the shear zone is at the critical void ratio. This condition also was rejected, since it would be very undesirable in a pavement.

At the minimum void ratio point, the rate of volume change within the sample is zero and no corrections are necessary due to this effect.

#### MATERIALS AND TESTING PROCEDURES

Two crushed stones were selected as representative of Iowa State Highway Commission approved crushed stone for rolled-stone bases. One is a weathered, moderately hard limestone of the Pennsylvania system. (Anderson and Welp, 1959) obtained from near Bedford, in Taylor County, Iowa (hereafter this will be referred to as the Bedford sample). The second is a hard dolomite of the Devonian system (Anderson and Welp, loc. cit.) obtained from near Garner, Hancock County, Iowa, and hereafter referred to as the Garner sample. Of the two, the Garner has the better service record.

X-ray diffraction analyses of powdered representative samples

showed calcite as the predominant mineral in both stones, but there was /.'/,/~ a considerable difference in calcite-dolomite ratio of  $\overline{F}$   $\overline{F}$  in the Bed- $1:25'$ ford stone and  $1:1:1:6$  in the Garner (Handy, 1965). X-ray tests on HCl-insoluble residues showed no montmorillonite in either sample, a small amount of 14  $\overset{\text{\normalsize O}}{A}$  mineral (vermiculite or chlorite) in the Garner, a predominance of illite in both, plus kaolinite and quartz. Kaolinite in the Bedford stone was poorly crystalline. The percent of insoluble residues was 10.9 in the Bedford and 6.7 in the Garner. pH's and cation exchange capacities of the whole samples were closely comparable.

Engineering properties of the two crushed stones are shown.in Table 1. The Bedford stone contains more gravel, less sand and more clay size particles, and has a measurable plasticity. The optimum moisture content for compaction is higher and the compacted density lower than for the Garner sample. The latter of course influences the void ratio, defined as the volume of voids divided by the volume of solids.

Four-inch diameter by 8-inch high specimens were prepared for triaxial testing by compacting the crushed stones to standard Proctor density in a vibratory mold.

The type of triaxial test used was the consolidated undrained test, in which the compacted, encased specimen is placed in the triaxial cell, the cell pressure is applied, and full consolidation is allowed to take place before testing. The drainage valve is then closed, and the axial load is applied at a constant strain rate of 0.01 in/min.

Similar procedures were employed to prepare and test the specimens compacted at modified Proctor density. These data are from the work of Best (1966) .

Table 1. Representative engineering properties of the two crushed stones..

•

 $\sim$   $\,$ 

The triaxial shear tests were run with continuous volume change and pore water pressure measurements. Data were reduced and plotted with the aid of computer programs.

#### ANALYSIS OF THE DATA

The results may be plotted as shown in Fig.  $l$ , where void ratios  $\sigma_{1}^{\prime}$  -  $\sigma_{3}^{\prime}$   $\sigma_{1}^{\prime}$  +  $\sigma_{3}^{\prime}$ are plotted versus the logarithms of  $\sigma'_{3c}$  ( $\frac{1}{2}$   $\frac{3}{2}$ ) and  $\frac{1}{2}$   $\frac{3}{2}$ ). Meanings of these terms are given in Appendix A. This form of presentation was originated during the Cooperative Triaxial Shear Research Program of the Corps of Engineers described by Rutledge (1947), and later used by Henkel (1959 and 1960) for tests on both normal and overconsolidated clays.

The consolidation history of the sample is taken into consideration in triaxial testing by means of the following equations, after Bishop and Henkel (1957) .

$$
\frac{\sigma_1^{\prime} - \sigma_3}{2 \sigma_2^{\prime}} = \frac{\cos \varphi^{\prime} r}{1 - \sin \varphi^{\prime} r} \cdot \frac{c^{\prime} r}{\sigma_2^{\prime}} + \frac{\sin \varphi^{\prime} r}{1 - \sin \varphi^{\prime} r} \cdot \frac{\sigma_3^{\prime}}{\sigma_2^{\prime}}
$$
(1)

$$
\frac{\sigma_1^{\prime} - \sigma_3^{\prime}}{2 \sigma_e^{\prime}} = C_1 + \tan \beta_1 \frac{\sigma_3^{\prime}}{\sigma_e^{\prime}}
$$
 (2)

where

$$
C_1 = \frac{\cos \varphi'_{r}}{1 - \sin \varphi'_{r}} \times \frac{c'_{r}}{\varphi_{e}^{+}} , \tan \beta_1 = \frac{\sin \varphi'_{r}}{1 - \sin \varphi'_{r}} \text{ and}
$$

 $\sigma_{\rm e}$ ' is the equivalent consolidation pressure. The equivalent consolida-

tion pressure corresponding to a void ratio e is defined as the pressure  $\sigma_{\rho}$ <sup>'</sup> for a point on the virgin branch of the consolidation diagram with the ordinate e.

Equation (1) may be transformed into:

•

$$
\frac{\sigma_1^{\;\;\prime} - \sigma_3^{\;\;\prime}}{2 \sigma_3^{\;\;\prime}} = C_2 + \frac{\sigma_1^{\;\;\prime} + \sigma_3^{\;\;\prime}}{2 \sigma_2^{\;\;\prime}} \quad \text{tan } \beta_2 \tag{3}
$$

where  $c''_r = \frac{c_2 \sigma_e'}{\cos \varphi'_{r}}$  and tan  $\beta_2 = \sin \varphi_r'$ . Equation (3) is used in this paper to determine  $c_r$  and  $\varphi_r$  .

The parameters  $\stackrel{\cdot}{\rm c}^{\ \cdot}_{\rm r}$  and  $\stackrel{\cdot}{\rm p}^{\ \cdot}_{\rm r}$  are termed, respectively, the "effective cohesion" and "effective friction" components of the shear strength, after Hvorslev (1937 and 1960). The effective cohesion component is a function of the effective consolidation pressure  $\sigma^{-\mathbf{v}}_{\mathbf{e}}$  , and therefore is a function of the void ratio. The effective angle of internal friction or effective friction component is a function of the effective normal stress, and is theoretically independent of the void ratio.

The components of shear strength defined in the foregoing paragraphs are primarily mathematical expressions of the results of shear tests, and may be called phenomenological components which have not yet been identified with specific intrinsic forces (Hvorslev, 1960).

The experimental determination of  $c_r^{\nu}$  and  $\varphi_r^{\nu}$  for saturated clays requires that samples fail at the same moisture content (or void ratio), but at different effective stresses to allow tangential fitting of an envelope to the different Mohr circles. This restriction does not allow the direct determination of  $c_r^{\dagger}$  and  $\varphi_r^{\dagger}$  in the laboratory. However, shear tests on normal and over-consolidated samples permit the

calculation of these parameters by means of equations (1) or (3) .

We may postulate that if the shear strength of a soil is indeed a function of its void ratio or water content, the line representing the locus of points of maximum shear stress versus void ratio or moisture content must be parallel to the line representing the virgin branch and/or the reloading or unloading branch of consolidation for the given soil. If this requirement is fulfilled for the soil being tested, then the shear strength is a unique function of the void ratio and effective stresses (Hvorslev, loc. cit.).

#### DISCUSSION

The data corresponding to the Bedford material are shown in Figs. 1-4. In addition to the usual consolidated-undrained tests, Bedford samples compacted at standard Proctor density were tested under consolidatedrepeated shear conditions. The repeated shear test was performed in the following manner: the normal load was applied at the constant axial strain rate to a maximum axial deflection of 0.075 inches, after which the axial strain was reversed and run at the same rate back to zero deflection. This process was repeated twice. The third loading was carried to failure and/or to constant sample volume.

Figures 1 and 2 indicate that the shear strength of the Bedford crushed stone is a function of the void ratio, since as stated in the previous section, the shear stress-void ratio function is parallel to the consolidation pressure-void ratio function. Therefore, the calculation of the parameters  $c_{\vec{r}}^{\phantom{\dagger}}$  and  $\phi_{\vec{r}}^{\phantom{\dagger}}$  is possible by a least squares fit

of equation (3), as shown in Fig. 3. Values obtained for these parameters are summarized in Table 2.

Table 2. Effective components of the shear strength of the Bedford stone.

The parameter  $\varphi_{r}$ ' for standard compaction differed very little in the two test procedures and the difference can be attributed to errors involved in testing and other approximations. For the purpose of discussion, the parameter  $\varphi_r$ ' is assumed to be the same for both testing procedures. Therefore, the strength difference between the two testing procedures is reflected in the values of the parameter  $c_{\vec{r}}$ '.

Figure 4 shows the relationship between the logarithm of  $c_{\vec{r}}$  and the minimum void ratio of the sample during shear for the Bedford crushed stone. The repeated loading process reduced the effective cohesion in each sample by 80% in comparison with the effective cohesion of the samples tested by the usual procedure. This reduction suggests a gradual change in the structure of the sample caused by the repeated loading process, and one may estimate that one more repetition might have reduced the sample to zero cohesion. It is observed in the same figure that this reduced cohesion value occurs in the same range of void ratios as the higher cohesion values of the samples tested by the usual method. Therefore the reduction in effective cohesion must

in fact be due to a change in the structure rather than difference in void ratio. "Structure" is understood to mean the arrangement of soil particles and the electrical forces acting between adjacent particles (Lambe, 1958).

The gradual change from a "cohesive structure" to a "cohesionless structure" seems to depend on the amount of shearing strain imposed on the sample rather than on the stress level. It is noteworthy to indicate that the stress-strain curves were modified by the repeated loading process. However, the significance of such a change in the stressstrain diagram is outside the scope of this paper.

Figure 4 also shows that the effective cohesion of the standard compacted and tested Bedford sample is constant through the higher range of void ratio, whereas at. lower values the effective cohesion becomes a linear function of the void ratio. The samples compacted at modified Proctor density also show a parallel linear relationship. Apparently a certain minimum compactness is required to achieve increasing cohesive strength with increasing density. The gradual change from a constant cohesion to a linearly increasing value with a decrease in void ratio probably indicates a change in structure.

Data corresponding to the Garner material are shown in Figs, 5-7. Example in the state of  $\sigma_1$ <sup>'</sup> -  $\sigma_3$ <sup>'</sup>  $\sigma_1$ <sup>'</sup> +  $\sigma_3$ <sup>'</sup> Figures 5 and 6 indicate that  $\frac{1}{2}$   $\frac{1}{2}$  and  $\frac{1}{2}$   $\frac{3}{2}$  again are linear functions of the void ratio; they are expressed by:

$$
\frac{\sigma_1' - \sigma_3'}{2} = 913 - 4075 e_{\text{min}}, \quad \text{for } e_{\text{min}} > 0.175 \tag{4}
$$

$$
\frac{\sigma_1' - \sigma_3'}{2} = 662.5 - 2640 e_{\min}, \quad \text{for } e_{\min} < 0.175 \tag{5}
$$

$$
\frac{\sigma_1' - \sigma_3'}{2} = 1129 - 5030 e_{\min'}.
$$
 (6)

The effective cohesion,  $c_r$ <sup>'</sup>, is zero for the Garner specimens. Therefore the friction component must be a function of the void ratio.

Figure 7 shows the relationship between sin  $\varphi'$  and the minimum void ratio, where sin  $\varphi$ <sup>'</sup> is given by the following equation:

$$
\frac{\sigma_1' - \sigma_3'}{2} = \frac{\sigma_1' + \sigma_3'}{2} \sin \varphi'
$$
 (7)

Figure 7 indicates that the angle of friction,  $\varphi$ ', increased as the void ratio decrease to a value 0.175. Once this void ratio was reached, there was a change in the relationship and  $sin~\varphi'$  decreased as the void ratio decreased. This change may be due to increased effective pressure causing crushing of interparticle contacts, reducing friction between the particles. The beneficial increase of  $sin~\varphi'$ with decrease in void ratio and increase in effective pressure may relate to an increasing number of interparticle contacts.

An interesting result is obtained when  $e_{min}$  is extrapolated to zero in equations  $(5)$  and  $(6)$ :

 $\frac{\sigma_1! \quad - \sigma_3!}{2}$  = 662.4 &  $\frac{\sigma_1! \quad + \sigma_3!}{2}$  = 1129, which gives sin  $\varphi!$  = 0.587 and  $\varphi' = 35.9^\circ$ .

The predominant mineral in the Garner crushed stone is calcite. Horn (1961) found the friction between surfaces of pure calcite submerged in water was  $34.3^{\circ}$ , by using a slider which applies shear force on three small "feet" sticking out of the highly polished contact surfaces. The purpose was to obtain an area of contact as small as possible.

Fig. 6. Garner stone: effective pressure and consolidation pressure as related to void ratio.

Fig. 7. Garner stone: values of  $sin \varphi'$ , and<br> $\varphi'$  as related to minimum void ratio.

A similar extrapolation can be made for the Bedford crushed stone, as shown in Table 3.

Table<sup>'</sup>3. Shear strength components of the Bedford crushed stone calculated at  $e_{\min} = 0$ .

Degree of Compaction Standard Proctor	Cohesion, psi 1171	Angle of Friction, deg. -36.5

Calcite is also the predominant mineral of the Bedford crushed stone. Von Karman (1911) performed triaxial tests on marble at very high cell pressure, up to 36,000 psi, and Bridgman (1936) and Griggs (1942) performed high pressure tests on calcite., The envelopes obtained are slightly curved and the mean results are summarized in Table 4. Table 4 also shows the results obtained for the Bedford material on the assumption that the friction angle was  $34.0^\circ$ , in order that a comparison could be drawn with the above quoted authors' results.

Table 4. Shear strength components of calcite for  $\sigma < 80,000$  psi.

The implication of the above comparisons is that the behavior of the Bedford and Garner stones belongs in two different systems; the

Garner extrapolates to pure sliding friction, whereas the Bedford extrapolates to sliding friction plus a cohesion comparable to values found in solid rock.

The exponential shear stress-void ratio function for the Bedford would appear to indicate increased cohesion caused by increased grain contact areas under higher pressures. This implies a compressibility of the Bedford stone particles. Under repeated loading, slight intergranular shear movements could perhaps cause the loss in cohesion, since grains would no longer be properly arranged or interlocked to cause an increase in contact areas with loading. That is, repeated compressions result in densification and a mass action rather than a point-contact building-block action of individual grains.

In the case of the Garner material, the shear stress-void ratio function is linear and therefore reflects the state of packing within the granular system. The friction parameter is therefore a measure of the interparticle interaction rather than the frictional characteristics of the particles. Thus most crushed stones, unlike the Bedford, tend to maintain strength under repeated loading.

#### **CONCLUSIONS**

•

 $\mathfrak{g}$ 

The shear-stress-void ratio function is an index to the behavior of compacted crushed stone materials under shear. Two different types of behavior are inferred: (a) compression of particle contacts under loading, increasing cohesion and giving an exponential relationship between shear strength and void ratio, and (b) sliding at point contacts

between particles, giving a linear relationship between shear strength and void ratio.

Behavior (a) apparently is not stable under repeated loading, since shear strength is gradually lost. This suggests a structural rearrangement of the grains which reduces grain-to-grain contact under pressure, and therefore cohesion. That is, the beneficial effect of consolidating pressures is gradually lost. Thus under repeated loading the behavior is similar to that of a clay.

In contrast, behavior (b) should be stable under repeated loading. The difference in behavior of the two stones thus may relate to the compression and shear character of the individual grain-to-grain surface contacts, which in turn should relate to some petrographic characteristics of the rock.

#### ACKNOWLEDGEMENTS

The research reported herein is a portion of a project on ''Factors Influencing Stability of Granular Base Course Mixes" under contract with the Iowa Highway Research Board, Iowa State Highway Commission and Bureau of Public Roads, U.S. Department of Commerce.

Appreciation is extended to the following organizations and personnel: to the Iowa Highway Research Board and Bureau of Public Roads for their continuing support of this project; to Mr. Steve Roberts, Director of Research, Mr. Tom McElherne, Materials Engineer, and Mr. Ted Welp, Geologist, Iowa State Highway Commission, for their valuable assistance and counseling; and to Dr. Turgut Demirel, Iowa State University, for his advice, interest, and criticisms.
