¹Work sponsored by the Iowa Coal Project and conducted in the Energy and Mineral Resources Research Institute at Iowa State University.

²University Year for ACTION volunteer.

ABSTRACT

Small mammal presence, diversity and reproduction were compared from August 1975 to June 1976 on abandoned coal strip-mine spoils and unmined land in southern Iowa. More species were snap-trapped on the unmined area, while the relative dominance of Peromyscus spp. on mined land was increased. Peromyscus populations on mined land exhibited a shorter breeding season than on unmined land. Other population parameters did not show clear differences between the areas.

Introduction

Approximately 4500 ha have been strip-mined for coal in Iowa, mostly in the southeastern part of the state. Strip mining eradicates the soil profile and plant and animal life by piling overburden in a series of long, parallel, steep ridges and narrow draws. The surface of the spoils is often characterized by high acidity (due to the oxidation of pyrites), unusual chemical concentrations, large temperature changes, low soil moisture and severe erosion; a generally harsh environment for mammals and other organisms prevails.

Lists of mammal species and estimates of their abundances on Illinois coal spoils were compiled by Yeager (1942) and Verts (1959). Verts (1957) and Wetzel (1958) found Peromyscus maniculatus dominant on younger Illinois spoils where weeds and grasses dominated the vegetation, while P. leucopus was dominant on older spoils with more shrubs and trees. Similar patterns were found in Indiana, but there was no correlation between species distribution and spoil age or soil conditions, since the nature of the spoils varied independently of age (Sly, 1976). Mumford and Bramble (1969) reported high densities of Peromyscus spp. and very low densities of other species on Indiana spoils. DeCapita and Bookhout (1975) found capture rates of several species (e.g. Peromyscus spp., Sylvilagus floridanus) comparable to or higher than those on mined land.

Most accounts of Iowa mammals are species lists and distributions, with little reference to population data. This study was undertaken to compare small mammal populations of abandoned Iowa coal spoils and nearby unmined land, in terms of species diversity, abundance and reproduction.

1 Study area. The abandoned strip-mined area was the Wilcox Wildlife
2 Preserve, SE Marion Co., about 250 ha mined between 1952 and 1962. The
3 unmined site was the area of the Iowa Coal Project Demonstration Mine
4 No. 1, in SW Mahaska Co., about 15 km east of the mined site.

5 The area has a rolling topography (elevation range approx. 180-300
6 m) drained by the Des Moines River system. Soils in the area are
7 alluvial in the valleys and river bottoms, Kansan till on the slopes and
8 loess on the hill-tops. Bottomlands and lower slopes were originally
9 vegetated with forest, and are now covered with secondary woods and
10 brush; some of the wider bottomlands are now in crops. The original
11 tall-grass prairie on the upper slopes has been replaced by crops and
12 pasture.

13 The climate of the area is characterized by cold winters and hot
14 summers. Mean annual temperature is 11° C; mean January temperature is
15 -5° C and mean July temperature is 25° C. Mean annual precipitation at
16 nearby Knoxville, Iowa (279 m elev.) is 830 mm, 70% of which falls in
17 the six months from April to September. The mean frost-free period is
18 170 days. During this study, winter snow cover was lower than usual,
19 and winter temperatures were warmer than normal.

Methods

Small mammal populations were sampled approximately monthly from August 1975 to July 1976 by snap-traps baited with peanut butter and oatmeal. Traplines of fifteen stations with two traps each were run five nights, except in September and October 1975, when only ten stations of three traps each were run four nights, at the unmined site only.

Animals were checked for reproductive condition and age.

Results

Abundance and diversity. Table 1 lists species abundance.

Peromyscus leucopus was the most abundant species both off and on coal spoils, followed by P. maniculatus. These species had a combined relative abundance of 56.1% off the spoils, and 86.9% on the spoils. The importance of Peromyscus spp. on the spoils is illustrated by a high concentration of dominance, as measured by Simpson's Index (Simpson 1949). The on-spoil index was 0.40, the off-spoil index was 0.22.

Eight other species were trapped in off-spoil habitats, and five others in on-spoil habitats (Table 1). Mus musculus, Cryptotis parva and Zapus hudsonius, found in off-spoil areas, were not captured on the spoils; however, presence of Mus and Cryptotis was indicated by examination of long-eared owl (Asio otus) pellets (Voight and Glenn-Lewin, in press).

Grassy habitats both off and on the spoils had a higher diversity of mammals than wooded habitats. P. maniculatus was the dominant species in grassy habitats of both areas (35.2% of the off-spoil capture, 48.1% of the on-spoil). In wooded habitats, P. leucopus was the most common species: 81.0% of the capture off the spoils, and 92.2% of the capture on the spoils. The wooded habitat at the unmined area was relatively young and open. Thus, some open-area species (e.g., P. maniculatus, Reithrodontomys megalotis) were found there.

Along spoil ridges, P. maniculatus constituted 54.8% of the capture, while P. leucopus made up 37.4%. Trapping in draws resulted in 61.7% P. leucopus, with 30.0% P. maniculatus. Thirty-nine percent of all Microtus pennsylvanicus were captured on ridges, although only 15% of the trap effort was exerted there. On spoil areas, Reithrodontomys

1 occurred only in well-vegetated draws and on small unmined remnant areas
2 within the spoils. Other species were captured in habitats expected for
3 those species.

4 Seasonal fluctuations in capture rates were found in both mined and
5 unmined areas (Table 2). Capture rates peaked in December, fell through
6 March, reached a secondary peak in May, and declined into summer. The
7 total unmined area capture rate was slightly lower than the on-spoil
8 rate (Table 1), although montly rates on the unmined area were somewhat
9 higher in September and from December through March (Table 2).

10 Reproduction. Both species of Peromyscus had shorter breeding
11 seasons on the coal spoils than in off-spoil habitats. In off-spoil
12 areas, males of both species were found with scrotal testes in all
13 months (with captures). On spoils, no scrotal testes were found in
14 male P. leucopus from November or December, and none in P. maniculatus
15 from November through February. No pregnant or lactating females were
16 found in off-spoil areas between November and February. In on-spoil
17 areas, no female P. leucopus were pregnant or lactating from November
18 through April; no P. maniculatus females appeared to be breeding from
19 November through March.

20 There was no difference between proportions of pregnant and
21 lactating females on the two sites for either Peromyscus spp. ($p > 0.05$).
22 Overall, 27.8% of the adult female P. leucopus were pregnant on the
23 spoils, 22.0% were pregnant off the spoils. Of adult female P.
24 maniculatus, 34.3% were pregnant on the spoils, 25.0% off the spoils.

25 Litter sizes were compared between the areas, but the samples were
26 small. Thirteen pregnant P. leucopus from on-spoil habitats averaged
27 4.9 embryos; five from off-spoil habitats averaged 3.6. Embryo counts

1 ranged from two to eight. Seventeen P. maniculatus on the spoils had an
2 average embryo count of 3.7, while three from unmined areas averaged 4.3
3 embryos. The P. maniculatus embryo count ranged from one to five.
4 These differences are not significant ($p > 0.05$).

5 No significant differences in Peromyscus spp. age ratios were
6 found between the two areas. Immatures were 23.5% of the P. leucopus
7 population and 28.5% of the P. maniculatus population on the spoils
8 area. Off the spoils area, immatures were 25.4% of the P. leucopus
9 population and 28.1% of the P. maniculatus population. The presence of
10 immatures in the trap sample during the winter non-breeding months was
11 probably due to carry-over of fall young.

12 Other parameters. The on-spoil sample of P. leucopus contained
13 58.4% males, the off-spoil population contained 47.4% males ($\chi^2 = 4.12$,
14 $p < 0.05$). Sex ratios of P. maniculatus from on and off spoil habitats
15 were not significantly different from an even ratio, nor from each
16 other (on-spoils 53.0% males, off-spoils 56.1% males). Of 53 immature
17 P. leucopus taken on the spoils, 61.8% were male; 39.3% of 28 off-spoil
18 immatures were male. Too few immature P. maniculatus were taken for
19 comparison.

20 There was no difference in average Peromyscus spp. body length,
21 compared by sex, between the mined and unmined areas. The same holds
22 for average body weights, except that the average body weight of P.
23 leucopus males was significantly less on the spoils (25.8g) than on
24 unmined land (27.5g; $p < 0.05$).

Discussion

Abundance and Diversity. As is typical of early successional stages in eastern North America (Beckwith, 1954; Pearson, 1959, Shure, 1970, Kirkland, 1976 and others), the two Peromyscus spp. are the dominant species on Iowa coal spoils, much more so than on off-spoil sites. Similar results have been reported by Yeager (1942), Verts (1957; 1959), Wetzel (1958), Mumford and Bramble (1969), De Capita and Bookhout (1975) and Sly (1976).

The two Microtus species show unexpected habitat affinities on the spoils. M. ochrogaster was expected to be more abundant, especially on dry ridges, but M. pennsylvanicus was found more often. Normally, M. ochrogaster is expected in drier habitats (Miller, 1969; Lewin, 1968). In off-spoil areas, normal habitat segregation of Microtus spp. was observed.

Species distribution was related to vegetational type. Habitat preference of P. leucopus for vertically structured areas and of P. maniculatus for open areas has been well documented (Dice, 1922; Blair, 1940; Jameson, 1949; Getz, 1961; Iverson et al, 1969 and others). In this study, P. leucopus were taken primarily near trees, fenceposts or rock outcroppings. The abundance of P. leucopus in draws (wooded) and the abundance of P. maniculatus on typically grassy ridges reflects the vegetation of these habitats. Ridges tend to be grassy due to heavy erosion and periodic desiccation that inhibits the growth of trees.

Reithrodontomys megalotis occurred both on and off the spoils usually in dense grass cover preferred by this species (Brummel, 1961; Birkenholz, 1967 and others).

DeCapita and Bookhout (1975) concluded that in spite of higher

1 capture rates of some species on spoil areas in Ohio, spoils were
2 inferior habitats to unmined land. This conclusion was based on the
3 high concentration of dominance and lower species richness of mammals on
4 spoils. The same holds for Iowa spoils, the low diversity correlating
5 with the low quality of coal spoil habitats.

6 Capture rates peaked in late fall and early winter, with a
7 secondary peak in late spring. Similar results have been reported (e.g.
8 Beer and MacLeod, 1966; Terman, 1968). The fall-winter peak has been
9 attributed to seasonal movements, the spring peak to the influx of
10 animals produced by spring breeding (Blair, 1940; 1948; Beer and
11 MacLeod, 1966).

12 Reproduction. On the spoils area, both Peromyscus spp. had a
13 shorter breeding season than on the unmined area. Orr-Ewing (1950), in
14 comparing P. leucopus populations from burned and clear-cut areas to
15 those of natural forests, found a shorter breeding season in the less
16 protected areas. Instances of extended winter breeding in Peromyscus
17 spp. have been reported in habitats with good cover and food supplies
18 and during mild winters (Linduska, 1942; Brown, 1945; Wood, 1910). Dif-
19 ferences in breeding seasons probably reflect differences in habitat
20 quality.

21 Litter sizes for P. leucopus are reported to be somewhat over four
22 (e.g., Burt, 1940; Svihla, 1932). The litter sizes for both areas for
23 P. leucopus were reasonably close to these figures. Reported litter
24 sizes for P. maniculatus from the Midwest range from 3.05 to 5.2
25 (Svihla, 1932; Linduska, 1942; Beer, et al, 1957; Beer and MacLeod,
26 1966; Long, 1968). The average of both areas for P. maniculatus in this
27 study was 3.79.

1 Other parameters. On Illinois coal spoils. Verts (1957) found 61%
2 of adult P. leucopus were male, and immatures were 30% male, similar to
3 the present results of 61.8% male adults and 39.3% males among immatures.
4 Verts (1957) found 61% of adult P. maniculatus were male, and immatures
5 were 56% male; present results show 53% males among adults, and
6 negligible differences between immatures on unmined areas and Verts'
7 (1957) data. Several studies have reported that males dominate the
8 immature age class (Jackson, 1952; Long, 1968; Beer and MacLeod, 1966);
9 this has been attributed to increased trap susceptibility of immature
10 males due to social pressures (Beer, et al, 1958).

11 Body sizes for both species are similar to other Iowa data (Sloan,
12 1964). The only significant variation between the two areas was found
13 in male P. leucopus, whose average weight was 1.7g less on the spoils
14 than off them. The reason for this is unknown.

Conclusions

This study analyzed field data for differences in species diversity, abundance, reproduction and population parameters of small mammals on strip-mined and unmined land in southeast Iowa. The main conclusions are:

1. Strip-mining lowers small mammal species diversity and changes the relative abundance of the species. The unmined land had ten species, while the mined area had seven. Also, the mined land had a greater percentage of captures of Peromyscus spp. than did the unmined area.
2. Peromyscus spp. breeding seasons were shorter on the mined area.
3. Age ratios, incidence of pregnancy and litter sizes of Peromyscus spp. did not significantly vary between the areas. Some differences in body size and sex ratios were noted, but overall the results were equivocal and no obvious trends were found.

1. The first part of the paper is devoted to a general
discussion of the problem. It is shown that the
problem is of great importance and that it has
not been completely solved. The author then
presents a new method for solving the problem.

2. In the second part of the paper, the author
applies the new method to a specific problem.
It is shown that the method is very effective
and that it can be used to solve a wide
variety of problems. The author then
presents a number of examples of problems
that can be solved using the new method.
The examples are chosen to illustrate the
strengths and weaknesses of the method.
The author concludes that the new method is
a valuable tool for solving problems of this
type.

3. The third part of the paper is devoted to a
discussion of the results of the work. It is
shown that the new method is very effective
and that it can be used to solve a wide
variety of problems. The author then
presents a number of examples of problems
that can be solved using the new method.
