## ACKNOWLEDGMENTS

This work was done under the support of the U.S. Department of Transportation, Federal Highway Administration (FHWA) Work Order Number DTFH71-94-TBL-IH-37 through the Iowa Department of Transportation (Iowa DOT), and the Iowa Highway Research Board (IHRB) as Project HR-559.

Project design and data collection were the result of the efforts of many persons at the Iowa DOT Central Materials, Design and Resident Construction Office in Cedar Rapids, Civil and Construction Engineering Department (CCE) at Iowa State University (ISU), the Statistics Department at Iowa State University, ERES Consultants and the Manatts Inc. concrete paving company. It would not have been possible without the assistance of John Hart of the Iowa Department of Transportation (Iowa DOT), and Tom Ciha of ISU. It has provided a learning experience for other students involved in the construction and monitoring including Marcia McCarthy, Tom Powers, and Adnan Ali. The project resulted in moving 2 students into the pavement area of transportation for a career. It also assisted approximately 12 other undergraduates in a better understanding of concrete pavement construction and into considering pavements for their area of interest prior to graduation.

This project is a great example of the research that is made available by the cooperation between the Iowa DOT, the Iowa Concrete Paving Association, and the department of Civil and Construction Engineering at ISU. Each party had faith in the abilities of the others and worked to extend the knowledge gained in the area of ultrathin overlays by the American Concrete Paving Association in Kentucky. It is another example of how Iowa is striving to lead in the area of portland cement concrete pavement research and development.

#### Abstract

In 1994 the Iowa Department of Transportation constructed a 7.2-mile Portland Cement Concrete overlay project in Iowa County on Iowa Highway 21. The research work was conducted in cooperation with the Department of Civil Engineering and the Federal Highway Administration under the Iowa Highway Research Board project HR-559. The project was constructed to evaluate the performance of an ultrathin concrete overlay during a 5-year period.

The experiment included variables of base surface preparation, overlay depth, joint spacing, fiber reinforcement, and the sealed or non-sealed joints. The project was instrumented to measure overlay/base interface temperatures and strains. Visual distress surveys and deflection testing were also used to monitor performance. Coring and direct shear testing was accomplished 3 times during the research period.

Results of the testing and monitoring are identified in the report. The experiment was very successful and the results provide an insight into construction and design needs to be considered in tailoring a portland cement concrete overlay to a performance need. The results also indicate a method to monitor bond with nondestructive methods.

Key Words: PCC overlay, ultrathin overlay, whitetopping

## 1. INTRODUCTION

### 1.1 Background

Portland cement concrete (PCC) whitetopping has been an effective method of pavement rehabilitation for many years. Whitetopping has been shown to provide improved structural capacity, increased life, and reduced maintenance, with lower total costs compared to asphalt cement concrete (ACC) pavement resurfacing. In addition, whitetopping improves safety by eliminating rutting and providing an excellent skid resistant surface and light reflectance. Environmental benefits are also realized through the use of whitetopping.

In recent years, ultra-thin whitetopping (UTW) has emerged as an alternative to traditional whitetopping. UTW is a process that involves placing a thin layer (2 to 4 inches) of PCC over an existing ACC pavement (so as not to confuse with unbonded overlays). Reduced PCC thickness and closer joint spacings distinguish UTW from traditional whitetopping. ${ }^{1}$

Initial UTW projects have enabled researchers to identify key elements responsible for the successful performance of UTW. These key elements include foundation support, interface bonding condition, PCC thickness, synthetic fiber reinforcement usage, and joint spacing. ${ }^{2}$ The interface bonding condition is the most important of these elements because it enables the pavement to act as a composite structure, thus reducing tensile stress and allowing an ultra-thin PCC overlay to perform adequately. ${ }^{3}$ Although the key elements affecting UTW performance have been identified in previous research, neither the impact that external variables have on the elements nor the element interaction, have been thoroughly investigated.

### 1.2 Objective of Research

The objective of this research was to investigate the interface bonding condition between an ultra-thin PCC overlay and an ACC base over time, considering the variables of ACC surface preparation, PCC thickness, synthetic fiber reinforcement usage, and joint spacing.

### 1.3 Research Approach

Laboratory testing and full-scale field testing were used to accomplish the research objective. Laboratory testing involved monitoring interface strains in fabricated PCC/ACC composite beams subjected to either static or dynamic flexural loading.

Field variables investigated included ACC surface preparation, PCC thickness, and synthetic fiber reinforcement usage. Field testing involved monitoring interface strains and temperatures, falling weight deflectometer (FWD) deflection responses, direct shear strengths, and distresses on a 7.2-mile Iowa DOT UTW project. Variables investigated included ACC surface preparation, PCC thickness, synthetic fiber reinforcement usage, and joint spacing.

## 2. TESTING PROGRAM

### 2.1 Laboratory Testing

Laboratory testing involved monitoring interface strains in fabricated PCC/ACC composite beams subjected to either static or dynamic flexural loading. Variables investigated included ACC surface preparation (milled or not milled), PCC thickness (2 or 4 inches), and synthetic fiber reinforcement usage (fiber or no fiber). Joint spacing was not evaluated in the laboratory testing. A total of $64 \mathrm{PCC} / \mathrm{ACC}$ composite beams were constructed. Half of the beams were used for static testing and half were used for dynamic testing. The static and dynamic test groups consisted of 8 sets of 4 beam groupings. The groupings were representative of the different variable combinations. Figure 2.1 illustrates the static and dynamic test groups and their beam groupings.

### 2.1.1 Beam Fabrication

Beam fabrication took place in Spangler Geotechnical Laboratory at Iowa State University. Fabrication of the beams involved designing the ACC and PCC mixes, mixing and placing the ACC, making and installing the deflectometers, and mixing and placing the PCC. Standard beam molds that were 6 inches wide by 6 inches deep by 36 inches long were used when fabricating beams with 2 inches of PCC. When beams with 4 inches of PCC were fabricated, standard beam molds were used with 2-inch wood extensions for added depth.

The materials and mix designs selected were similar to those used in the field testing. Mixing and placement of the ACC was accomplished by hand. The ACC was placed in 4 lifts, resulting in a thickness of approximately 3.75 inches. Deflectometers were fabricated

Figure 2.1 Static and Dynamic Test Groups and Their Beam Groupings
devices used to measure strains. Each deflectometer consisted of a 4 inch long by 0.5 inch wide piece of 26 gage steel, 2 Micro-Measurement type CEA-06-125-UN-120 strain gages, two 10-foot segments of AT\&T shielded telephone wire, a 1 inch cube of aluminum tubing, a 1.5 inch long piece of 0.125 inch diameter thread-all, and four 0.125 inch diameter nuts.

Figure 2.2 details the dimensions of the steel piece and location of the strain gages. Figure 2.3 shows an assembled deflectometer. Two deflectometers were installed in each beam.

Figure 2.2 Location of Strain Gages on a Steel Piece

Figure 2.3 Assembled Deflectometer

The deflectometers were placed vertically in epoxy filled holes with the faces of the steel piece parallel to the ends of the beam. The holes were 3 inches deep, 0.75 inches in diameter, 6 inches on center from the ends of the beam, and centered across the width of the beam. Figure 2.4 provides a schematic of an installed deflectometer prior to PCC placement. Figure 2.5 shows the installed deflectometers prior to PCC placement. Mixing of the PCC was

Figure 2.4 Schematic of an Installed Deflectometer Prior to PCC Placement

Figure 2.5 Installed Deflectometers Prior to PCC Placement
accomplished using a drum mixer. The PCC was placed by hand and consolidated with the use of a vibrating table. All PCC was placed in 1 lift, resulting in a thickness of approximately 2 or 4 inches. Beam molds were removed after at least 1 day of curing.

### 2.1.2 Testing Device

Testing was conducted in the ISU Aerospace Testing Laboratory using a device consisting of a 55 kip Materials Testing System (MTS) capable of static or dynamic loading, a 3-part loading frame, and a data acquisition system (DAS). The MTS and the 3-part loading frame were used to impart the load onto the beams and the DAS was used to control and monitor testing. The same testing device was used for static and dynamic testing.

The MTS had a fixed top load head and a moving bottom load head. The moving bottom load head allowed for loads to be imparted onto the beam and deflections to be measured. The 3-part loading frame consisted of 2 steel base plates and a solid steel cage.

Figure 2.6 shows the MTS and the 3-part loading frame. The DAS consisted of a personal computer, a MTS control and data recording program, and a Vishay voltage amplifier.

Figure 2.6 MTS and Three-Part Loading Frame

### 2.1.3 Static Testing

Static testing was conducted prior to dynamic testing. The primary objective of static testing was to determine the appropriate load magnitudes to be used for dynamic testing for each beam grouping. Secondary objectives of static testing included monitoring interface strains during loading and visually observing failure modes.

Static testing began by aligning the base plates and then gripping their flanges with the load head clamps. A neoprene covered roller pin was positioned on the bottom base plate. The beam was placed squarely onto the bottom base plate with the PCC in contact with the neoprene covered pins. Initial attempts to place the beams with the ACC on the bottom resulted in the ACC failing in tension while being handled. A neoprene covered
roller pin was positioned on the ACC and then the bottom load head was raised until contact was initiated between the ACC and the pins of the top base plate. Strain gages were connected and balanced. The MTS control and data recording program was then used to apply a constant rate of deflection of 0.05 inches per second until failure occurred.

### 2.1.4 Dynamic Testing

Dynamic testing was conducted after static testing had been completed and the appropriate load magnitudes for each beam grouping had been determined. The primary objective of dynamic testing was to monitor interface strains at varying levels of load repetitions. A secondary objective of dynamic testing was to visually observe failure modes if they occurred.

The beam placement procedure used in the static testing was also used in dynamic testing with the exception that the loading cage was placed around the beam after the beam had been placed onto the bottom base plate and that a preloading of 30 to 40 pounds was applied when contact was initiated. The cage and preloading helped to prevent the beam and roller pins from shifting during loading. The MTS control and data recording program was used to apply an oscillating load. The load was applied for 0.05 seconds and then removed for 0.05 seconds. This timing was selected to simulate loading of traffic traveling over a 3foot length of pavement at 60 mph . At increments of 10,000 applied repetitions, the MTS control and data recording program automatically stopped applying the oscillating load and initiated a ramp load. The ramp load was applied or removed at a constant rate of 20 pounds

Figure 2.7 Ramp Load Application
per second. Figure 2.7 depicts the ramp load application. Table 2.1 shows the oscillating and peak ramp load magnitudes used for each beam grouping. Strains were only measured during ramp loading. This sequence was continued until failure occurred or 100,000 repetitions were applied.

### 2.2 Field Testing

Field testing involved monitoring interface strains and temperatures, FWD deflection responses, direct shear strengths, and visual distresses on an UTW project. Variables investigated included ACC surface preparation (milled, patch only, or cold in place recycle (CIPR)), PCC thickness ( $2,4,6$, or 8 inches), synthetic fiber reinforcement usage (fiber or no fiber), and joint spacing ( $2,4,6$, or 12 foot square panels). The UTW project consisted of 65 sections, including 35 test, 27 transition, and 3 control sections. Variables remained constant in test sections and were 200 to 2700 feet in length with most sections being 700 feet long. Transition sections were located between test sections and allowed for changes in variables to occur. Control sections consisted of conventional ACC overlays. Table 2.2 shows the section locations and design properties. Table 2.3 shows a comparison of design properties for several UTW projects.

Table 2.2 Section Locations and Design Properties

### 2.2.1 Location and History

The project was located south of the City of Belle Plaine, Iowa, in Iowa County on a 7.2 mile stretch of Iowa Highway 21 from US 6 to Iowa Highway 212. Figure 2.8 illustrates the project location. This portion of Iowa Highway 21 is a 2-lane roadway 24 feet in width with 9-foot granular shoulders and ditch drainage. The existing alignment was graded in 1958. A granular driving surface was used until 1961, at which time improvements were made. The improvements included replacing the original subgrade with select soil material 24 inches in depth and 24 feet wide on center, covering the select soil material with 6 inches of granular material beneath 7 inches of cement treated sand (CTS) beneath 0.75 inches of chip seal all 24 feet wide on center, and constructing 9 -foot granular shoulders. The chip seal was used as the driving surface until 1964, when 3 inches of Type B ACC was placed on top

Figure 2.8 Project Location
of it. In 1987, a seal coat of negligible thickness was applied to the ACC surface.
Construction of the UTW project occurred in 1994. All pavement layers were designed and placed according to effective Iowa State Highway Commission (ISHC) or Iowa DOT specifications at the time of contract letting. Figure 2.9 shows the pavement layers and the years of their construction.

### 2.2.2 Soil Conditions

According to the Iowa County Soil Survey Report, Fayett-Downs, Tama-Downs, and Colo-Bremer-Nevin-Nodaway soil associations occur along the project. ${ }^{4}$ Fayett-Downs and Tama-Downs are the primary associations along the project. These associations were formed from loess, are generally well drained, and have moderate to high shrink/swell potential.

Figure 2.9 Pavement Layers and Their Construction Years

They are fair subgrade soils. The Colo-Bremer-Nevin-Nodaway association is along a small portion of the project. This association was formed from alluvium, is generally poorly to moderately drained, and has moderate to high shrink/swell potential. It is an unsuitable subgrade soil.

More detailed soil information was obtained from a soil survey conducted by the ISHC prior to the 1958 grading operations. Soil borings were taken approximately every 100 feet in cut areas. The soils found were primarily fine grained and had American Association of State Highway and Transportation Officials (AASHTO) classifications ranging from A-6 (6) to A-7-6 (20). Soils with these classifications are fair to poor subgrade soils and have moderate to high shrink/swell and frost heave potential. Some very limited pockets of A-1-b, A-2-4, A-3, and A-4 soils were found. Based on the survey findings, select soil treatment for
the entire project was specified in the 1961 improvements. Table 2.4 details the class names and AASHTO classifications of project soils.

### 2.2.3 Climate Conditions

The climate in Iowa County is subhumid with seasonal variations in temperature and moisture. ${ }^{4}$ Rapid changes in weather are frequently experienced throughout the year due to the convergence of 2 major storm tracks. Typically, the winters are cold and the summers are hot. Prolonged periods of extreme temperatures are rare. January is typically the coldest and driest month with an average temperature of $19.9^{\circ} \mathrm{F}$ and an average precipitation of 1.28 inches. ${ }^{5}$ July is normally the hottest month with an average temperature of $75.0^{\circ} \mathrm{F}$. The average yearly precipitation is 30.70 inches. Two-thirds of the precipitation occurs from April to June with the seasonal peak in June. Frost penetration in the area is approximately 60 inches.

### 2.2.4 Traffic Loading

The project is located along a portion of Iowa Highway 21 that serves primarily as a farm to market road and as an access route for US 6. Private residences and a few intersections with lightly traveled county roads exist along the project. No commercial or
industrial sites are present to create large fluxes in traffic or uneven directional usage. Historic Iowa DOT average daily traffic (ADT), average daily truck traffic (ADTT), classification counts, and typical vehicle axle configurations and weights were used to estimate traffic loading using the same methods used to supply annual traffic information to the Federal Highway Administration (FHWA). In 1994, the average ADT was 1,090 and the average ADTT was 142 . Figure 2.10 shows the ADT and ADTT observations and growth trends for Iowa Highway 21. Figure 2.11 shows the percent of traffic for each IDOT vehicle classification.

Figure 2.10 ADT and ADTT Observations and Growth Trends for Iowa Highway 21

Figure 2.11 Percent of Traffic for Each IDOT Vehicle Classification

A weigh-in-motion (WIM) station was located midway through the project in each lane. Although the WIM equipment did experience some sporadic outages due to mechanical and software problems, data were obtained for the majority of each year during the research. The WIM data were used to calculate Equivalent Single Axle Loads (ESALs) based on AASHTO damage factors for 6 inch PCC. For both lanes, ESALs were found to increase each year and their totals were nearly balanced. Table 2.5 shows the ESALs by year and in total for each lane.

Table 2.5 ESALs by Year and in Total for Each Lane

| Year | Northbound ESALs | Southbound ESALs |
| :---: | :---: | :---: |
| 1995 | 2,865 | 9,328 |
| 1996 | 10,468 | 14,394 |
| 1997 | 12,337 | 23,394 |
| 1998 | 28,248 | 41,379 |
| 1999 | 57,410 | 42,456 |
| Total | 111,328 | 130,744 |

### 2.2.5 Construction

The project was constructed in the spring and summer of 1994 and conformed to Iowa DOT specifications and special provisions noted in the project contract. Conventional construction procedures and equipment were used to complete the project. Materials used underwent regular assurance testing to guarantee quality constraints were met. In addition, PCC paving operations were subjected to plant and grade inspections, ACC paving operations were subjected to plant inspections and district lab testing, and CIPR surface preparation was subjected to district lab testing. Appendix A provides a summary of pertinent inspection and testing results. Previously submitted documents should be consulted for a more detailed review of the project construction, testing, and inspection. ${ }^{1,6,7}$

### 2.2.6 Pavement Instrumentation

Pavement instrumentation was done approximately 500 feet in front of the paving operations. Test sections were instrumented for the purpose of obtaining strain and temperature measurements. No ACC control sections were instrumented. Approximately $75 \%$ of the sites were located in the northbound lanes and $25 \%$ were in the southbound lanes. Table 2.6 shows the location and as-built properties of the sites selected for instrumentation.

Table 2.6 Location and As-Built Properties of Sites Selected for Instrumentation

| Section Number | Site Number | Station | PCC Design Thickness (in.) | Actual PCC Thickness (in.) | Synthetic Fiber Usage | Joint Spacing (ft. X ft.) | ACC <br> Surface <br> Preparation |

\end{array}
$$

At each site, 2 deflectometers and a thermocouple were installed. The deflectometers were identical to those used in the laboratory testing, except the length of the AT\&T telephone wire was 30 feet. A description of the deflectometer fabrication process and of the deflectometers can be found on page 4. The thermocouples used were type IRAD GAGE TH-1. The thermocouples were completely assembled by the manufacturer and consisted of a thermistor covered in high impact epoxy and encapsulated in an extruded stainless steel shell. A 30 foot shielded cable with 2 copper lead wires was soldered to the thermistor sensor wires.

Pavement instrumentation began by using a tape measure to accurately locate the station of the site. Offset measurements from the located station and the edge of pavement were then made to determine the exact positioning of the deflectometers. For all sites, the positioning of the deflectometers relative to the edge of pavement and a transverse joint were identical. The deflectometers were installed using the same procedure as in the laboratory testing, except the deflectometers were oriented at right angles to each other. A description of the deflectometer installation procedure can be found on page 5 . Figure 2.12 provides a schematic and the orientation of installed deflectometers prior to PCC placement. The thermocouple was placed horizontally on the ACC between the deflectometers.

After the instrumentation was installed, a shallow trench with a downward slope away from the roadway was made. The trench extended from the edge of the pavement through the foreslope. A piece of 2-inch diameter PVC pipe was cut that would extend the length of the trench and protrude slightly out of the foreslope. Wiring from the instrumentation was fed through the pipe. The pipe was sealed at the pavement end and capped with a threaded nut at

Figure 2.12 Schematic and Orientation of Installed Deflectometers Prior to PCC Placement
the foreslope end. Drain holes were drilled in the bottom of the pipe at the foreslope. Gage wires were labeled A through D according to their position. The pipe was placed in the trench and the trench was backfilled.

### 2.2.7 Strain and Temperature Testing

Strain and temperature testing was conducted during and after the construction of the project. During construction, testing progressed with paving operations. Each instrumented site was tested twice per construction day for 2 weeks after the site had been paved and then once a week thereafter until construction was completed. Testing started at about 9:00 A.M. and then again at about 12:00 noon. After construction, testing was conducted 3 times a year. Typically, the test dates were the first Saturday in May, August, and November. Each site was tested once, and testing started at about 9:00 A.M. All testing proceeded from the south to the north. The objective of strain and temperature testing was to monitor interface strains in relation to the bonding condition over time and at various pavement temperatures.

At each site, testing began by removing the cap from the PVC pipe and exposing the instrumentation wiring. Gage wires were individually connected to a P-3500 strain indicator allowing each strain to be measured and then recorded. Thermocouple lead wires were connected to an IRAD GAGE TH-1 temperature sensor unit and the interface temperature was measured and recorded.

### 2.2.8 Falling Weight Deflectometer Testing

FWD testing was conducted before and after the construction of the project. Before construction, the original pavement structure was tested in the outer wheel path of the north and southbound lanes every 300 feet and at locations selected for instrumentation. Each location was tested once. After construction, the new pavement structure was tested at instrumented sites in the center of panels located in the outer wheel path of the instrumented lane. Each location was tested once a year in the last week of July, starting in the year of construction. All testing started at about 9:00 A.M. and proceeded from the south to the
north. In addition to normal testing, special testing was conducted in areas where debonding was suspected or probable. The objective of FWD testing was to monitor deflection responses in relation to the bonding condition over time.

Testing was conducted by ERES Consultants Incorporated of Champaign, Illinois using a Dynatest Model 8081 FWD with a segmented 5.9-inch radius load plate and 7 seismic transducers. One transducer was located at the center of the load plate (D0) while the others were spaced at radial 12-inch intervals (D1, D2, D3, D4, D5, and D6). A van equipped with a closed circuit television (CCTV), computer, and system processor was used to pull the FWD trailer. The CCTV aided the van driver in positioning the load plate. The computer and system processor controlled testing operations and recorded maximum deflection responses measured by each transducer.

Testing began by preparing the FWD testing device and setting the computer stationing to the start point stationing. The distance the van traveled was directly linked to the stationing displayed and recorded on the computer. Tracking of the distance traveled by the van was initiated when the start point was reached. At each test location, the van driver positioned the load plate using the CCTV. The computer was then used to lower the load plate and transducers onto the pavement surface and initiate the load sequence. The load sequence consisted of a seating load followed by test loads of approximately 6,9 , and 12 kips. The different loads were obtained by varying the drop height of the weight. Figure 2.13 details the FWD loading apparatus.

Figure 2.13 FWD Loading Apparatus

### 2.2.9 Direct Shear Testing

Direct shear testing was added to the initial scope of field testing and was conducted when the project was 3 and 5 years old. Future testing is scheduled when the project will be 7 years old. Sections selected for testing had 2-inch PCC design thicknesses and provided a sampling of the different variable combinations. Testing was conducted on 6 cores taken from each selected section. Coring was done on panels positioned in the outer wheel path of the northbound lane. Three cores each were obtained from the center and interior corner positions of the panels. Separate panels were used for each core. Table 2.7 details the core locations and section design properties. Special testing was conducted in areas where debonding was suspected or probable. The primary objective of direct shear testing was to
quantitatively measure the interface bond over time. A secondary objective of direct shear testing was to visually observe the interface bonding condition.

Table 2.7 Core Locations and Section Design Properties

$\mathrm{M}=$ monofilament fibers

Coring was conducted using the Iowa DOT drilling rig. The rig was mounted on the back of a single unit truck, which contained a water and mortar supply. The drilling apparatus was turned by the power supply of the rig and consisted of a 4 inch diameter diamond drill bit attached to the end of a rotational shaft. The drill bit was water cooled and was supported by a rigid guide foot. An assembly of bearings allowed direct contact to be made between the guide foot and the rotating drill bit. An inverse hydraulic jack system was used to impart drilling pressure.

Coring began by locating and marking the core locations. At each core location, the drill apparatus was positioned and then the inverse hydraulic jack was lowered until it made contact with the PCC. Rotation of the drill bit and water flow was initiated and then the drill
bit was lowered into contact with the PCC. A safe drilling pressure and a moderate and constant rotational speed was maintained. When drilling reached an adequate depth, the drill bit was withdrawn while still rotating. Water and rotation were terminated and the core was removed from the drill bit or the hole. The hole was filled with mortar. Cores were transported back to the Iowa DOT Central Materials Laboratory where they were photographed, measured, and tested.

Equipment used for testing included a MTS, a testing jig, and a holder clamp. The MTS had a fixed top load head and a moving bottom load head. The moving bottom load head allowed for a smooth and uniform tensile load to be applied to the testing jig. The testing jig was made of 2 separate steel plates with 4 -inch diameter holes. Connected to each steel plate was a gripping shaft and a channel. The shafts were capable of being gripped by the MTS load heads and were offset to the center so that eccentric loading would not occur. The channels provided guidance for the plates and ensured that a small space existed between the steel plates. The holder clamp was attached to the channels and allowed the cores to be rigidly held in place during testing. Figure 2.14 depicts the MTS and testing jig required to perform Iowa DOT Test Method 406-C.

Figure 2.14 MTS and Testing Jig

Testing began by aligning the testing jig in the MTS. Care was taken to ensure the central axis of the testing jig was aligned with the central axis of the MTS. When the alignment was correct, the load heads were used to clamp the gripping shafts. This procedure was conducted at the startup of testing and was only repeated if the testing jig became misaligned. The core was placed in the testing jig with the interface positioned in the space between the steel plates. The holder clamps were then fastened to the core and a tensile load in the range of 400 to 500 psi per minute was applied until failure occurred. After the failure occurred, the failure load was recorded and the failed core was removed.

### 2.2.10 Visual Distress Surveys

Visual distress surveys were conducted after the construction of the project. Both lanes of every section of the project were completely surveyed. Surveys entailed a person walking on each shoulder recording the type and location of every observed distress. The types of distresses considered in the survey included transverse cracks, longitudinal cracks,
corner cracks, diagonal cracks, popouts, joint spalls, and fractured panels. Surveys typically were conducted on the first Saturday in February, May, August, and November. All surveys started at about 9:00 A.M. and proceeded from the south to the north. In addition to normal surveys, driving surveys were conducted periodically by local roadway maintenance personnel. Driving surveys focused on identifying potentially hazardous fractured panels with debonded PCC. The primary objective of visual distress surveys was to monitor distresses in relation to the serviceability and bonding condition over time. Areas of high distress in which debonding had occurred, was suspected, or was probable were targeted for additional investigation with aforementioned testing.

## 3. ANALYSIS AND RESULTS

### 3.1 Introduction

Analysis of the field and lab data was focused on providing results on the interface bonding condition between an ultra-thin PCC overlay and an ACC base over time, considering the variables of ACC surface preparation, PCC thickness, synthetic fiber reinforcement usage, and joint spacing. Data preparation, statistical treatment, results, and insights have been discussed in detailed. Analysis and results of strain and temperature as well as falling weight deflectometer testing are based on the first 3 years of a scheduled 5year program. Analysis and results of all other testing is based on 5 years of a scheduled 5year program.

### 3.2 Static Testing

Static testing was conducted prior to dynamic testing. The primary objective of static testing was to determine the appropriate load magnitudes to be used for dynamic testing for each beam grouping. Secondary objectives of static testing included monitoring interface strains during loading and visually observing failure modes.

### 3.2.1 Data Preparation

Static data from each beam were assembled into individual Excel spreadsheets. For each beam, load and deflection versus time as well as shear strain versus time were plotted. The plots were reviewed for erroneous data resulting from reading errors or invalid deflections. Erroneous data were removed and were given no further consideration. The load and deflection versus time plot was used to determine the time of ultimate load. Shear
strain and load values occurring at the time of ultimate load were referenced. All data obtained were input on a summary sheet.

Ultimate load data were used to develop a theoretical analysis of shear strain and maximum normal stresses for bonded and unbonded conditions. Calculations were done on an Excel spreadsheet. For all theoretical analyses the following assumptions were made:

1. Material properties were constant
2. PCC and ACC thicknesses were constructed as specified
3. Epcc $=3,700,000 \mathrm{psi}$
4. $\mathrm{Eacc}=145,000 \mathrm{psi}$

Pictures of tested beams and a testing journal were used to categorize observed failure modes. Four failure modes were identified and are defined as follows:

1. Localized crack failure - complete cross-sectional break of beam
2. Localized end failure - compression of ACC in region of pins
3. Layer separation - unbonding of ACC and ACC interface
4. Interface separation - unbonding of ACC and PCC interface

### 3.2.2 Statistical Treatment and Results

While assembling the static data into individual Excel spreadsheets it was discovered that entire data files were overwritten or lost. In addition, gage 3 was found to be producing erroneous data for all beams while gages 1,2 , and 4 produced erroneous data intermittently. Due to premature ACC tensile failure resulting from loading the beams with the ACC on the bottom, no data existed for beams with 2-inch PCC, not milled, and no fiber. Considering the substantial amount of unusable data it was determined that a meaningful evaluation could only be made on combined thickness beam groupings of 2 and 4-inch PCC. Figure 3.1 shows the percent of strain gages producing usable data for detailed and combined thickness beam groupings. Graphical comparisons of averages were used to evaluate the data.

Average experimental ultimate loads for 2 and 4 -inch PCC used to determine the
appropriate load magnitudes for dynamic testing can be found in Figure 3.2. As anticipated, 2-inch PCC had lower average experimental ultimate load and shear strain than 4-inch PCC. Regardless of the PCC thickness small average experimental shear strains were produced. The magnitude of the ultimate loads combined with strain gage orientation resulted in the small shear strains. Small shear strains coupled with the inherent noise in the equipment setup made measurement and evaluation difficult. Figure 3.3 illustrates the small shear strains and equipment noise encountered.

Figure 3.1 Percent of Strain Gages Producing Usable Data for Detailed and Combined Thickness Groupings of Static Beams

Figure 3.2 Average Experimental Ultimate Load and Shear Strain for 2 and 4-Inch PCC of Static Beams

Figure 3.3 Small Shear Strains and Equipment Noise Encountered for Static Beams
Theoretical and average experimental shear strains at average ultimate load for
bonded and unbonded conditions of 2 and 4 -inch PCC are shown in Figure 3.4. Theoretical shear strains obtained by modeling a bonded condition closely approximated average experimental shear strains, indicating that a bonded condition was maintained through

Figure 3.4 Theoretical and Average Experimental Shear Strains at Average Ultimate Load for Bonded and Unbonded Conditions of 2 and 4-Inch PCC of Static Beams
failure. Figure 3.5 details PCC and ACC maximum theoretical normal stresses at average ultimate load for bonded and unbonded conditions of 2 and 4 -inch PCC. When bonded conditions exist, maximum theoretical normal stresses of the PCC are small and unequal while those of the ACC are similar and of reasonable ultimate value. These observations indicate that localized crack failure initiated in the ACC as a result of ACC tension. This assessment is further substantiated considering the maximum theoretical normal stresses of the PCC with unbonded conditions are similar and of reasonable value for PCC tensile
failure.

Figure 3.5 PCC and ACC Maximum Theoretical Normal Stresses at Average Ultimate Load for Bonded and Unbonded Conditions of 2 and 4-Inch PCC of Static Beams

Figure 3.6 shows the percent of observed failure modes for conditions of 2 and 4 -inch PCC. All beams tested exhibited localized crack failure. Localized end failure occurred for both 2 and 4 -inch PCC conditions, with 4-inch PCC having a slightly higher incidence. As a result of localized end failure, testing conditions were altered prematurely and confidence in load, deflection, and strain data was diminished. Layer separation occurred with more than twice the frequency and with more severity than interface separation. This relationship was noted for only the 2-inch PCC condition. It is not understood why it was not observed for the 4-inch PCC condition. Regardless, more frequent and severe occurrences of layer separation

Figure 3.6 Percent of Observed Failure Modes for Conditions of 2 and 4-Inch PCC of Static Beams
indicate that conditions were more critical in the ACC than at the interface and that a bonded condition was predominant through failure.

### 3.3 Dynamic Testing

Dynamic testing was conducted after static testing had been completed and the appropriate load magnitudes for each beam grouping had been determined. The primary objective of dynamic testing was to monitor interface strains at varying levels of load repetitions. A secondary objective of dynamic testing was to visually observe failure modes if they occurred.

### 3.3.1 Data Preparation

Dynamic data from each beam were assembled into individual Excel spreadsheets. All data were organized in order of runs, with each run consisting of 10,000 applied oscillating loads followed by a ramp load application. For each beam, deflection and shear strain data versus number of observations of each run were plotted. The plots were reviewed for erroneous data resulting from reading errors or invalid deflections. Erroneous data were removed and were given no further consideration. Raw load data were used to determine the magnitude and time of peak ramp load for all runs. Shear strains occurring at the time of peak ramp load were referenced. All data obtained were input on a summary sheet.

Peak ramp load data were used to develop a theoretical analysis of shear strain for bonded and unbonded conditions over the application of applied oscillating loads. Calculations were done on an Excel spreadsheet. For all theoretical analyses the following assumptions were made:

1. Impact of dynamic loading could be ignored
2. Material properties were constant
3. PCC and ACC thicknesses were constructed as specified
4. $\mathrm{Epcc}=3,700,000 \mathrm{psi}$
5. $\mathrm{Eacc}=145,000 \mathrm{psi}$

Pictures of tested beams and a testing journal were used to categorize observed failure modes. Failure modes identified for dynamic testing are identical to those of static testing. A description of the failure modes can be found on page 33 .

### 3.3.2 Statistical Treatment and Results

While assembling the dynamic data into individual Excel spreadsheets it was discovered that entire data files were overwritten or lost. In addition, gage 3 was found to be producing erroneous data for all beams while gages 1,2 , and 4 produced erroneous data
intermittently. No data existed for beams with 2 or 4 -inch PCC, not milled, and no fiber. Considering the substantial amount of unusable data it was determined that a meaningful evaluation could only be made on combined thickness beam groupings of 2 and 4 -inch PCC.

Figure 3.7 shows the percent of strain gages producing usable data for detailed and combined thickness beam groupings. Graphical comparisons of averages in conjunction with regression were used to evaluate the data.

Figure 3.7 Percent of Strain Gages Producing Usable Data for Detailed and Combined Thickness Groupings of Dynamic Beams

Average applied oscillating and peak ramp loads for detailed beam groupings can be found on page 11. Average oscillating loads were approximately half of the average ultimate loads for 2 and 4-inch PCC static testing. Figure 3.8 shows average applied oscillating and
peak ramp loads for conditions of 2 and 4-inch PCC. For 2-inch PCC, average oscillating and peak ramp loads were similar; however, for 4-inch PCC average peak ramp loads were

Figure 3.8 Average Applied Oscillating and Peak Ramp Loads for Conditions of 2 and 4Inch PCC of Dynamic Beams
half the magnitude of average oscillating loads. The reason for this discrepancy was not understood. Figure 3.9 shows the average number of applied oscillating loads prior to failure for conditions of 2 and 4 -inch PCC. The 2 -inch PCC had a greater average number of applied oscillating loads prior to failure than the 4 -inch PCC. This observation is not surprising considering that the oscillating load magnitude of the 4 -inch PCC is nearly 5 times that of the 2 -inch PCC. Due to the use of different oscillating and peak ramp loads, direct comparisons between 2 and 4 -inch PCC was difficult.

Regardless of the PCC thickness small experimental shear strains were produced. The magnitude of the peak ramp loads combined with strain gage orientation resulted in the

Figure 3.9 Average Number of Applied Oscillating Loads Prior to Failure for Conditions of 2 and 4-Inch PCC of Dynamic Beams
small shear strains. Small shear strains coupled with the inherent noise in the equipment setup made measurement and evaluation difficult. Figure 3.10 illustrates the small shear strains and equipment noise encountered for various runs. To limit noise and provide distinct shear strain values at the time of peak ramp load, piecewise linear regression was used.

Figure 3.11 shows shear strain data after piecewise linear regression was applied.

Figure 3.10 Small Shear Strains and Equipment Noise Encountered for Various Runs of Dynamic Beams

Figure 3.11 Shear Strain Data After Piecewise Linear Regression was Applied to Various Runs of Dynamic Beams

Theoretical and average experimental shear strains at peak ramp load for bonded and unbonded conditions of 2-inch and 4-inch PCC are shown in Figure 3.12 and Figure 3.13 respectively. For 2 and 4-inch PCC over the application of oscillating loads, theoretical shear strains obtained by modeling a bonded condition more closely approximated average experimental shear strains, indicating that a bonded condition was maintained. Second order polynomial regression applied to the average experimental shear strains shows an upward trend for both 2 and 4-inch PCC as the number of applied oscillating loads increase. These observations reveal that conditions became more critical as a result of fatigue. The $R^{2 .}$ values for the second order polynomial regression indicate the robustness of the data was adequate.

Figure 3.12 Theoretical and Average Experimental Shear Strains at Peak Ramp Load for Bonded and Unbonded Conditions of 2-Inch PCC of Dynamic Beams

Figure 3.13 Theoretical and Average Experimental Shear Strains at Peak Ramp Load for Bonded and Unbonded Conditions of 4-Inch PCC of Dynamic Beams

To facilitate a direct comparison of shear strains between 2 and 4-inch PCC, applied oscillating loads were normalized to 4 -inch PCC conditions. Previously developed second order polynomial regression equations were used to predict shear strains of 2 and 4-inch PCC with the normalized oscillating loads. Figure 3.14 details predicted shear strains for conditions of 2 and 4-inch PCC. As oscillating loads increased, predicted shear strains for 2inch PCC increased more rapidly than for 4-inch PCC, showing that 2-inch PCC is more susceptible to fatigue. It should be noted that comparisons were only made to 30,000 oscillating loads due to a lack of data substantiating the regression equation for more oscillating loads.

Figure 3.14 Predicted Shear Strains Using Normalized Oscillating Loads for Conditions of 2 and 4-Inch PCC of Dynamic Beams

Figure 3.15 shows the percent of observed failure modes for conditions of 2 and 4inch PCC. Localized end failure was the only observed failure for 4-inch PCC and the average number of applied oscillating loads was extremely low. These two observations imply that 4-inch PCC loading conditions severely overstressed contact points on the ACC resulting in premature failure. Due to the premature failure, comparisons of 2 and 4 -inch PCC could not be made. All types of failures were observed for 2-inch PCC and the number of average applied oscillating loads was moderate. These two observations imply that 2-inch PCC loading conditions overstressed contact points on the ACC after a substantial number of oscillating loads had been applied.

Figure 3.15 Percent of Observed Failure Modes for Conditions of 2 and 4-Inch PCC of Dynamic Beams

### 3.4 Strain and Temperature Testing

The objective of strain and temperature testing was to monitor interface strain in relation to the bonding condition over time and at various pavement temperatures. Due to limitations in time and expertise in complex structural modeling, efforts of this research concentrated on assembling data and identifying variables that most significantly impacted strains. This information will be helpful in focusing future modeling and evaluation efforts.

### 3.4.1 Data Preparation

Strain and temperature data from each site were assembled into an Excel spreadsheet. The data were reviewed for erroneous measurements resulting from reading errors or nonfunctioning gages. Erroneous measurements were removed and given no further
consideration. Strain averages were calculated for gages on the same deflectometer. The final pour date and test dates were used to determine the age at testing. Data were separated into individual Excel spreadsheets based on opening time. Postopening time was considered postconstruction, while preopening time was considered construction. Postconstruction was the only data analyzed, ensuring the pavement system was stabilized. Plots of individual, average, and mean average strains versus PCC thickness, joint spacing, ACC surface preparation, synthetic fiber reinforcement usage, temperature, and age, were developed.

Data assembled on the Excel spreadsheet were copied into SPSS. Average strains were identified as the dependent variable. PCC thickness, joint spacing, ACC surface preparation, and synthetic fiber reinforcement usage were identified as factors. Levels within each factor were assigned dummy variables. Table 3.1 details how dummy variables were assigned. Temperature and age were considered covariates.

Table 3.1 Dummy Variable Assignment for Strain and Temperature Data

| Factor | Level | Dummy Variable |
| :--- | :--- | :---: |
| PCC Thickness Grouping | 3 | 0 |
| (in.) | 5 | 1 |
|  | 7 | 2 |
| Joint Spacing | $2 \times 2$ | 0 |
| (ft. X ft.) | $4 \times 4$ | 1 |
|  | 6 X 6 | 2 |
| ACC Surface Preparation | 12 X 12 | 3 |
|  | Milled | 0 |
|  | Patch Only | 1 |
|  | CIPR | 2 |
|  | No Fiber | 0 |
|  | Fiber | 1 |

### 3.4.2 Statistical Treatment and Results

While assembling the strain and temperature data into an Excel spreadsheet it was discovered that $27 \%$ of the gages became nonfunctioning over time. In addition, 6 sites were completely destroyed by grading or maintenance mowing operations over time. Statistical analysis was difficult because of the large number of variables, lack of repetition, and incomplete matrix in the experimental design. Considering these factors as well as the loss of data over time, it was determined that an easier and more meaningful evaluation could be made by grouping data based on PCC thickness. Table 3.2 details how the PCC thicknesses were grouped.

Table 3.2 PCC Thickness Groupings for Strain and Temperature Data

| PCC | PCC Thickness <br> Grouping <br> Thickness <br> (in.) |
| :---: | :---: |
| $\mathrm{T} \leq 4$ | 3 |
| $4>\mathrm{T} \leq 6$ | 5 |
| $\mathrm{~T}>6$ | 7 |

$$
\mathrm{T}=\mathrm{PCC} \text { thickness }
$$

Strain and temperature versus age for site 1 and 29 are shown in Figure 3.16 and Figure 3.17 respectively. Site locations and as-built properties can be found on page 22 . These sites were selected because their as-built properties are drastically opposite and their data were representative of the behavior of almost all of the sites. Temperature followed a regular up and down pattern clearly related to seasonal changes. Strains were constant in compression or tension until the age of approximately 480 days. At this time, a movement

Figure 3.16 Temperature and Strain Versus Age for Site 1

Figure 3.17 Temperature and Strain Versus Age for Site 29
into tension occurred along with increased magnitude. Strains remained at this elevated level of tension until approximately 760 days, when they returned to less compressive and more tensile conditions to those encountered before 480 days.

The substantial movement into tension may have occurred from a sudden widespread event or testing errors. The widespread nature of the event implies a connection to environmental conditions. Considering that the change occurred in 1995 between the months of August and November, temperature data shown were reviewed. Major temperature differentials did occur during September and October of 1995. Complex structural modeling may reveal the impact of these temperature differentials. The change is unlikely to have occurred from testing errors considering that all testing conditions were kept constant and the change was observed over an extended period of time. These observations indicate that temperature and age do impact strain.

Appendix $B$ contains plots of average strain AB and CD versus PCC thickness, joint spacing, ACC surface preparation, synthetic fiber reinforcement usage, temperature, and age. The plots revealed slight relationships between average strains and PCC thickness, ACC surface preparation, temperature, and age. No relationships were observed between average strains and joint spacing or synthetic fiber reinforcement usage. The plots also revealed the existence of several outlying data points.

To compare the effect of PCC thickness, joint spacing, ACC surface preparation, synthetic fiber reinforcement usage, temperature, and age on average strains in detail, 2-way factorial analysis of variance with interaction was conducted. Individual 2-way factorial analysis of variance with interaction was used to limit complexity and make interactions more interpretable. PCC thickness was believed to be the most influential factor and
therefore was used in all analyses. A significance level of 0.05 was used.
Boxplots in conjunction with histograms were used to evaluate whether the data were normally distributed. Examining the means for patterns of variance was used to evaluate whether the data exhibited equal variance. None of the data were found to be normally distributed or of equal variance. In an effort to satisfy the assumptions, outlying data points above the $99^{\text {th }}$ percentile were examined and removed if considered erroneous and then a log transformation was applied. The log transformed data satisfied the assumptions of being normally distributed and of equal variance the best and therefore was used in all analyses.

Analyses were conducted by leaving missing data blank and by replacing missing data with factor level averages. A substantial difference was not observed when the two approaches were compared; therefore, results from leaving the missing data blank are discussed herein. Appendix B contains ANOVA tables for each individual 2-way factorial analysis of variance with interaction. Table 3.3 summarizes the results of the analyses. The results indicate the following:

1. None of the models adequately explain the variance in the dependent variable
2. The factor of ACC surface preparation was significant for AB
3. The factor of joint spacing was significant for CD
4. The covariate temperature was significant for all models
5. The covariate age was significant for all models of CD

Considering none of the models adequately explained the variance in the dependent variable, additional models were explored with varying combinations of factors and covariates. None were found to explain the variance in the dependent variable better than those presented in Table 3.3. All factors except synthetic fiber reinforcement usage were

Table 3.3 Summary of Two-Way Factorial Analysis of Variance with Interaction for Transformed Average Strain AB and CD

| Strain | Model | Significant <br> Factors Or <br> Covariates | Model/Total <br> Sum Of <br> Squares |  |
| :--- | :--- | :--- | :---: | :--- |

$\mathrm{FU}=$ synthetic fiber usage
explored independently using 1-way analysis of variance with post HOC tests. Synthetic fiber reinforcement usage was explored using a 2-sample T test. A significance level of 0.05 was used. Methods similar to those previously mentioned were used to evaluate whether the data were normally distributed and of equal variance. The data were found to satisfy the assumptions. Appendix B contains multiple comparison tables for each individual 1-way analysis of variance with post HOC tests and a table for the 2 -sample T test. Table 3.4 summarizes the results of the analyses. The results indicate the following:

1. Patch only surface preparation is significantly different from CIPR surface preparation for AB .
2. 4-foot joint spacing is significantly different from 6 -foot joint spacing for CD.

The results concur with those obtained from the 2-way factorial analysis of variance with interaction. However, it is difficult to interpret the reason for and the meaning of the significant comparisons observed. No explanation can be provided as to why significant comparisons were not observed for both average strain AB and CD . The clarity

Table 3.4 Summary of One-Way Analysis of Variance With Post HOC Tests and TwoSample T Test for Transformed Average Strain AB and CD

| Strain | Factor | Significant Level | Compared To Level |
| :--- | :--- | :---: | :---: |
| AB | T | - | - |
|  | JS | - | - |

| CD | FU | - | - |
|  | T | - | - |
|  | JS | 4 | 6 |
|  | SP | - | - |
|  | FU | - | - |

$$
\begin{array}{ll}
\mathrm{T}=\mathrm{PCC} \text { thickness } & \mathrm{SP}=\text { ACC surface preparation } \\
\mathrm{JS}=\text { joint spacing } & \mathrm{FU}=\text { synthetic fiber usage }
\end{array}
$$

and meaning of the results are further diminished from the occurrence of significance for comparisons that are similar rather than dissimilar.

Graphical comparisons of mean average strain AB and CD were used to explore PCC thickness, joint spacing, ACC surface preparation, synthetic fiber reinforcement usage, temperature, and age in more general terms. Temperature and age versus mean average strains for 3, 5, and 7-inch PCC are shown in Figure 3.18 and Figure 3.19 respectively. All PCC thicknesses showed elevated mean average strains at low temperatures. At intermediate temperatures all PCC thicknesses had moderate and fairly constant mean average strains. At higher temperatures, 5 and 7-inch PCC displayed more variable and lower mean average strains while 3-inch PCC displayed moderate mean average strains. For all PCC thicknesses, a change in mean average strains at an age of approximately 480 days occurred. A discussion
about this change can be found on page 49. Mean average strains from before and after the change reveal a slight increasing trend and more variability as age increases for all PCC

Figure 3.18 Mean Average Strain AB and CD Versus Temperature for 3, 5, and 7-Inch PCC

Figure 3.19 Mean Average Strain AB and CD Versus Age for 3, 5, and 7-Inch PCC
thicknesses. These observations indicate that temperature and age do impact strain. In particular, extreme temperatures and periods with drastic temperature changes appear to be the most influential.

Mean average strains versus PCC thickness are shown in Figure 3.20. Slightly higher mean average strains were observed as PCC thickness increased. This phenomenon was also observed across factors of joint spacing and ACC surface preparation as well as the covariates of temperature and age. Figure 3.21 shows mean average strains versus joint spacing for 3, 5, and 7-inch PCC. As joint spacing increased mean average strains were decreased for all PCC thicknesses. Observations for PCC thickness and joint spacing are

Figure 3.20 Mean Average Strain AB and CD Versus PCC Thickness

Figure 3.21 Mean Average Strain AB and CD Versus Joint Spacing for 3, 5, and 7-Inch PCC
contrary to conventional PCC pavement theory. Complex structural modeling may reveal the reason for these transgressions. Figure 3.22 shows mean average strains versus ACC surface preparation for 3, 5, and 7-inch PCC. For all PCC thicknesses, elevated mean average strains were observed for patch only surface preparation while milled and CIPR surface preparations had lower, similar mean average strains. No reason can be provided for these observations. Figure 3.23 shows mean average strains versus synthetic fiber reinforcement usage for 3, 5, and 7-inch PCC. No discernable trends were observed for synthetic fiber reinforcement usage.

Figure 3.22 Mean Average Strain AB and CD Versus ACC Surface Preparation for 3, 5, and 7-Inch PCC

Figure 3.23 Mean Average Strain AB and CD Versus Synthetic Fiber Usage for 3, 5, and 7-Inch PCC

### 3.5 Falling Weight Deflectometer Testing

The objective of FWD testing was to monitor deflection responses in relation to the bonding condition over time. Several back calculation techniques were investigated to model and evaluate bonded and unbonded conditions but none were found that appropriately represented UTW. Due to the limitations of available backcalculation techniques, efforts of this research concentrated on assembling data and identifying variables that most significantly impacted deflection responses.

### 3.5.1 Data Preparation

FWD data from each testing period were assembled into an Excel spreadsheet. The data were reviewed for erroneous measurements resulting from reading errors. No erroneous measurements were found. Data were organized by station, date, and applied load. Observations of D4, D5, and D6 were removed because the upper pavement region, measured by D0, D1, D2, and D3, was the only area of interest. In addition, D4, D5, and D6 were often positioned across joints, resulting in variable conditions due to load transfer differences. Only data for an applied load of 9 kips were analyzed, considering deflection responses would only be shifted up or down as a result of different load magnitudes. Deflection responses were normalized to exactly 9 kips using a linear relationship.

Percent reductions in deflection responses for each testing period after UTW construction were calculated. Deflection responses before UTW construction were used as the baseline. The use of percent reduction in deflection responses eliminated any bias resulting from variations in existing foundation support. Changes in percent reduction in deflection responses between testing periods were calculated. Deflection responses immediately after UTW construction were used as the baseline. Plots of percent reduction in
deflection responses and changes in percent reduction in deflection responses versus PCC thickness, joint spacing, ACC surface preparation, synthetic fiber reinforcement usage, and age were developed.

Data assembled on the Excel spreadsheet were copied into SPSS. Percent reduction in deflection responses and changes in percent reduction in deflection responses were identified as dependent variables. PCC thickness, joint spacing, ACC surface preparation, and synthetic fiber reinforcement usage were identified as factors. Levels within each factor were assigned dummy variables. Dummy variables assigned can be found on page 48. Age was considered a covariate.

### 3.5.2 Statistical Treatment and Results

Statistical analysis was difficult because of the large number of variables, lack of repetition, and incomplete matrix in the experimental design. Considering these factors, it was determined that an easier more meaningful evaluation could be made by grouping data based on PCC thickness. PCC thickness groupings used for strain and temperature testing were believed to be appropriate and were employed. PCC thickness groupings can be found on page 49 .

### 3.5.2.1 Percent Reduction in Deflection Responses

Appendix C contains plots of percent reduction in deflection responses D0, D1, D2, and D3 versus PCC thickness, joint spacing, ACC surface preparation, and synthetic fiber reinforcement usage. The plots revealed substantial relationships between percent reduction in deflection responses and PCC thickness and joint spacing. No relationships were observed between percent reduction in deflection responses and ACC surface preparation or synthetic
fiber reinforcement usage. The plots also revealed the existence of outlying data points.
To compare the effect of PCC thickness, joint spacing, ACC surface preparation, and synthetic fiber reinforcement usage on percent reduction in deflection responses in detail, 2way factorial analysis of variance with interaction was conducted. Individual 2-way factorial analysis of variance with interaction was used to limit complexity and make interactions more interpretable. PCC thickness was believed to be the most influential factor and therefore was used in all analyses. A significance level of 0.05 was used.

Boxplots in conjunction with histograms were used to evaluate whether the data were normally distributed. Examining the means for patterns of variance was used to evaluate whether the data exhibited equal variance. Percent reduction in deflection responses D0 and D1 were found to only marginally satisfy assumptions of normality and equal variance. In an effort to satisfy the assumptions more fully, outlying data points above the $99^{\text {th }}$ percentile were examined and removed if considered erroneous and then a log transformation was investigated. None of the outlying data points were found to be erroneous. The transform did not improve the data with respect to satisfying the assumptions; therefore, the nontransformed data were considered acceptable and are discussed herein.

Appendix C contains ANOVA tables for each individual 2-way factorial analysis of variance with interaction. Table 3.5 summarizes the results of the analyses. The results indicate the following:

1. All of the models adequately explain the variance in the dependent variable
2. The factor of thickness was significant for all models

Table 3.5 Summary of Two-Way Factorial Analysis of Variance With Interaction for Percent Reduction in Deflection Responses D0, D1, D2, and D3

| Radial Distance | Model | Significant Factors | $\begin{gathered} \hline \text { Model/Total } \\ \text { Sum Of } \\ \text { Squares } \\ \hline \end{gathered}$ | Notes |

$\begin{array}{ll}\mathrm{T}=\text { PCC thickness } & \mathrm{SP}=\mathrm{ACC} \text { surface preparation } \\ \mathrm{JS}=\text { joint spacing } & \mathrm{FU}=\text { synthetic fiber usage }\end{array}$

All factors except synthetic fiber reinforcement usage were explored independently using 1-way analysis of variance with post HOC tests. Synthetic fiber reinforcement usage was explored using a 2 -sample T test. A significance level of 0.05 was used. Methods similar to those previously mentioned were used to verify that the data were normally distributed and of equal variance. Appendix C contains multiple comparison tables for each individual 1-way analysis of variance with post HOC tests and a table for the 2-sample T test. Table 3.6 summarizes the results of the analyses. The results indicate the following:

1. 3-inch PCC is significantly different from 5 and 7 -inch PCC for D0, D1, D2, and D3
2. 12-foot joint spacing is significantly different from 2 and 6 -foot joint spacing for $\mathrm{D} 0, \mathrm{D} 1$, D2, and D3
3. 4-foot joint spacing is significantly different from 6-foot joint spacing for D2
4. No fiber sections are significantly different from sections with fiber for D2 and D3

Table 3.6 Summary of One-Way Analysis of Variance With Post HOC Tests and TwoSample T Test for Percent Reduction in Deflection Responses D0, D1, D2,
and D3

| Radial Distance | Factor | Significant Level | Compared To Level |
| :--- | :--- | :---: | :---: |

|  | T | 3 | 5,7 |
|  | JS | 12 | 2,4 |
|  | SP | - | - |
|  | FU | No Fiber | Fiber |

$$
\begin{array}{ll}
\mathrm{T}=\mathrm{PCC} \text { thickness } & \mathrm{SP}=\text { ACC surface preparation } \\
\mathrm{JS}=\text { joint spacing } & \mathrm{FU}=\text { synthetic fiber usage }
\end{array}
$$

The results concur with those obtained from the 2-way factorial analysis of variance with interaction for PCC thickness. The significant comparisons observed for joint spacing are explained from the inherent relationship of larger joint spacing for thicker PCC. No explanation can be provided as to why the significant comparisons for synthetic fiber usage are observed. The repeated significance of comparisons for all radial distances coupled with the occurrence of significance for comparisons that are dissimilar enhanced the clarity and meaning of the results.

Graphical comparisons of mean percent reduction in deflection responses D0, D1, D2, and D3 were used to explore PCC thickness, joint spacing, ACC surface preparation, and synthetic fiber reinforcement usage in more general terms. Mean percent reduction in deflection responses versus PCC thickness are shown in Figure 3.24. Substantially higher
mean percent reduction in deflection responses were observed as PCC thickness increased. This phenomenon was also observed across factors of joint spacing, ACC surface preparation, and synthetic fiber reinforcement usage. These observations indicate that PCC thickness is the primary factor controlling deflection responses initially. As the PCC became thicker, the rate of increase in mean percent reduction in deflection responses diminished. This suggests that an optimal PCC thickness exists.

Figure 3.24 Mean Percent Reduction in Deflection Responses D0, D1, D2, and D3 Versus PCC Thickness

Figure 3.25 shows mean percent reduction in deflection responses versus joint spacing for 3 , 5, and 7-inch PCC. For 3-inch PCC, mean percent reduction in deflection responses decreased as joint spacing increased. For 5 and 7-inch PCC, mean percent reduction in deflection responses increased as joint spacing increased. These observations indicate that thinner PCC dissipates loads more effectively with smaller joint spacing while

Figure 3.25 Mean Percent Reduction in Deflection Responses D0, D1, D2, and D3 Versus Joint Spacing for 3, 5, and 7-Inch PCC
thicker PCC dissipates loads more effectively with larger joint spacing. This is explained by considering the load dissipation method in relation to PCC thickness. Loads are dissipated by compression for smaller joint spacing and by bending for larger joint spacing. Thicker PCC can resist bending more effectively and therefore reduces deflections more effectively with larger joint spacing. Thinner PCC cannot resist bending as well and therefore reduces deflections more effectively with smaller joint spacing through compression. Figure 3.26 shows mean percent reduction in deflection responses versus ACC surface preparation for 3, 5, and 7-inch PCC. For 3 and 7-inch PCC, elevated mean percent reduction in deflection responses were observed for patch only surface preparation while milled and CIPR surface

Figure 3.26 Mean Percent Reduction in Deflection Responses D0, D1, D2, and D3 Versus ACC Surface Preparation for 3, 5, and 7-Inch PCC
preparations had lower, similar mean percent reduction in deflection responses. These observations indicate that the milling and CIPR provide less structure initially. Milling provides less structure due to the removal of ACC material while CIPR provides less structure because it is recently placed and has not age hardened. Figure 3.27 shows mean percent reduction in deflection responses versus synthetic fiber reinforcement usage for 3,5 , and 7-inch PCC. For 3-inch PCC, no fiber had higher mean percent reduction in deflection responses. No explanation for this observation can be provided. Trends were not observed for synthetic fiber reinforcement usage, for 5 and 7 -inch PCC.

Figure 3.27 Mean Percent Reduction in Deflection Responses D0, D1, D2, and D3 Versus Synthetic Fiber Usage for 3, 5, and 7-Inch PCC

### 3.5.2.2 Change in Percent Reduction in Deflection Responses

Appendix D contains plots of changes in percent reduction in deflection responses D0, D1, D2, and D3 versus PCC thickness, joint spacing, ACC surface preparation, synthetic fiber reinforcement usage, and age. The plots revealed a substantial relationship between change in percent reduction in deflection responses and PCC thickness. No relationships were observed between change in percent reduction in deflection responses and joint spacing, ACC surface preparation, synthetic fiber reinforcement usage, or age. In addition, the plots revealed the existence of a few outlying data points.

To compare the effect of PCC thickness, joint spacing, ACC surface preparation, synthetic fiber reinforcement usage, and age on change in percent reduction in deflection responses in detail, 2-way factorial analysis of variance with interaction was conducted.

Individual 2-way factorial analysis of variance with interaction was used to limit complexity and make interactions more interpretable. PCC thickness was believed to be the most influential factor and therefore was used in all analyses. A significance level of 0.05 was used.

Boxplots in conjunction with histograms were used to evaluate whether the data were normally distributed. Examining the means for patterns of variance was used to evaluate whether the data exhibited equal variance. Change in percent reduction in deflection responses D0, D1, D2, and D3 were found to satisfy the assumption of normality but only marginally satisfied the assumption of equal variance. In an effort to satisfy the assumption of equal variance more fully, outlying data points above the $99^{\text {th }}$ percentile were examined and removed if considered erroneous and then a log transformation was investigated. None of the outlying data points were found to be erroneous. The transform did not improve the data with respect to satisfying the assumption of equal variance; therefore, the nontransformed data were considered acceptable and is discussed herein.

Appendix D contains ANOVA tables for each individual 2-way factorial analysis of variance with interaction. Table 3.7 summarizes the results of the analyses. The results indicate the following:

1. All of the models adequately explain the variance in the dependent variable
2. The factor of thickness was significant for all models except T/FU/AGE for D3
3. The factor of joint spacing was significant for all models except for D2
4. The factor of ACC surface preparation was significant for all models except for D3
5. The covariate of age was significant for all models of D2

Table 3.7 Summary of Two-Way Factorial Analysis of Variance With Interaction for Change in Percent Reduction in Deflection Responses D0, D1, D2, and D3

| Radial <br> Distance | Model | Significa <br> nt Factors | Model/Total <br> Sum Of <br> Squares | Notes |
| :--- | :--- | :--- | :---: | :--- |
| D0 | T/JS/AGE | T, JS | 0.340 | Incomplete Matrix |
|  | T/SP/AGE | T, SP | 0.393 | Interaction Was Significant |
| D1 | T/FU/AGE | T | 0.220 | - |
|  | T/JS/AGE | T, JS | 0.245 | Incomplete Matrix |
|  | T/SP/AGE | T, SP | 0.429 | Interaction Was Significant |
| D2 | T/FU/AGE | T | 0.202 | - |
|  | T/JS/AGE | T, AGE | 0.363 | Incomplete Matrix |
|  | T/SP/AGE | T, SP, AGE | 0.437 | Interaction Was Significant |
| D3 | T/FU/AGE | T, AGE | 0.329 | - |
|  | T/JS/AGE | JS | 0.305 | Incomplete Matrix |
|  | T/SP/AGE | T | 0.193 | Interaction Was Significant |
|  | T/FU/AGE | - | 0.161 | - |

$\begin{array}{ll}\mathrm{T}=\mathrm{PCC} \text { thickness } & \mathrm{SP}=\text { ACC surface preparation } \\ \mathrm{JS}=\text { joint spacing } & \mathrm{FU}=\text { synthetic fiber usage } \\ \text { AGE }=\text { age } & \end{array}$

All factors except synthetic fiber reinforcement usage were explored independently using 1-way analysis of variance with post HOC tests. Synthetic fiber reinforcement usage was explored using a 2 -sample T test. A significance level of 0.05 was used. Methods similar to those previously mentioned were used to verify that the data were normally distributed and of equal variance. Unequal variance of change in percent reduction in deflection responses D0, D1, D2, and D3 was observed for some factors. Results from Tamhane's multiple range test and 2 -sample T test equal variances not assumed were used when unequal variances occurred. Appendix D contains multiple comparison tables for each individual 1-way analysis of variance with post HOC tests and a table for the 2-sample T test. Table 3.8 summarizes the results of the analyses. The results indicate the following:

1. 3-inch PCC is significantly different from 5 and 7 -inch PCC for D0, D1, D2, and D3
2. 12-foot joint spacing is significantly different from 2 and 6 -foot joint spacing for D0, D1, D2, and D3
3. 4-foot joint spacing is significantly different from 6-foot joint spacing for D2
4. No fiber sections are significantly different from sections with fiber for D2 and D3

Table 3.8 Summary of One-Way Analysis of Variance With Post HOC Tests and TwoSample T Test for Change in Percent Reduction in Deflection Responses D0, D1, D2, and D3

| Radial Distance | Factor | Significant Level | Compared To Level |
| :--- | :--- | :---: | :---: |
| D0 | T | 3 | 5,7 |
|  | JS | 6 | 4 |
|  | SP | - | - |
| D1 | FU | No Fiber | Fiber |
|  | T | 3 | 5,7 |
|  | JS | 6 | 4 |
|  | SP | Milled | CIPR |
| D2 | FU | No Fiber | Fiber |
|  | T | 3 | 5,7 |
|  | JS | 6 | 2 |
|  | SP | - | - |
| D3 | FU | No Fiber | Fiber |
|  | T | 3 | 5,7 |
|  | JS | 6 | $2,4,12$ |
|  | SP | - | - |
|  | FU | No Fiber | Fiber |

$$
\begin{array}{ll}
\mathrm{T}=\mathrm{PCC} \text { thickness } & \mathrm{SP}=\text { ACC surface preparation } \\
\mathrm{JS}=\text { joint spacing } & \mathrm{FU}=\text { synthetic fiber usage }
\end{array}
$$

The results concur with those obtained from the 2-way factorial analysis of variance with interaction for PCC thickness. The significant comparisons observed for joint spacing are explained from the inherent relationship of larger joint spacing for thicker PCC coupled with how loads are dissipated relative to joint spacing and PCC thickness. No explanation can be provided as to why significant comparisons are not observed for ACC surface preparation but are observed for synthetic fiber usage. The repeated significance of
comparisons for all radial distances coupled with the occurrence of significance for comparisons that are dissimilar enhanced the clarity and meaning of the results.

Graphical comparisons of mean change in percent reduction in deflection responses D0, D1, D2, and D3 for year 3 were used to explore PCC thickness, joint spacing, ACC surface preparation, and synthetic fiber reinforcement usage in more general terms. Only year 3 was considered because it was representative of all other ages and allowed for the most recent data to be presented. Mean change in percent reduction in deflection responses versus PCC thickness are shown in Figure 3.28. Substantially lower mean change in percent

Figure 3.28 Mean Change in Percent Reduction in Deflection Responses D0, D1, D2, and D3 Versus PCC Thickness
reduction in deflection responses were observed as PCC thickness increased. This phenomenon was also observed across factors of joint spacing, ACC surface preparation, and synthetic fiber reinforcement usage. These observations indicate that PCC thickness is the primary factor controlling deflection responses over time. As the PCC became thicker, the
rate of decrease in mean change in percent reduction in deflection responses diminished. This suggests that an optimal PCC thickness exists.

Figure 3.29 shows mean change in percent reduction in deflection responses versus joint spacing for 3, 5, and 7-inch PCC. Mean change in percent reduction in deflection responses increased as joint spacing increased for 3-inch PCC and decreased for 5-inch PCC. These observations can be explained by how loads are dissipated and indicate that less

Figure 3.29 Mean Change in Percent Reduction in Deflection Responses D0, D1, D2, and D3 Versus Joint Spacing for 3, 5, and 7-Inch PCC
efficient methods of load dissipation result in increased deflections responses over time. For 7-inch PCC, mean change in percent reduction in deflection responses increased as joint spacing increased. This observation cannot be explained; however, magnitudes were extremely small and other factors may have shown their influence.

Figure 3.30 shows mean change in percent reduction in deflection responses versus

ACC surface preparation for 3, 5, and 7-inch PCC. For 3 and 5-inch PCC, elevated mean change in percent reduction in deflection responses were observed for CIPR surface preparation while milled and patch only surface preparations had lower, similar mean change in percent reduction in deflection responses. These observations indicate that the milling and

Figure 3.30 Mean Change in Percent Reduction in Deflection Responses D0, D1, D2, and D3 Versus ACC Surface Preparation for 3, 5, and 7-Inch PCC
patch only maintain their structure better over time. They do so because they are age hardened and more stabilized. For 7-inch PCC, elevated mean change in percent reduction in deflection responses were observed for milled and patch only surface preparations. This observation cannot be explained; however, magnitudes were extremely small and other
factors may have shown their influence. Figure 3.31 shows mean change in percent reduction in deflection responses versus synthetic fiber reinforcement usage for 3,5 , and 7 inch PCC. For all PCC thicknesses, mean changes in percent reduction in deflection responses were less for no fiber. No explanation for this observation can be provided.

Figure 3.31 Mean Change in Percent Reduction In Deflection Responses D0, D1, D2, and D3 Versus Synthetic Fiber Usage For 3, 5, and 7-Inch PCC

### 3.5.3 Base Prewetting

The asphalt base surface was wet in sections 1-11, immediately in front of the paving machine. Water was sprayed on the surface with a hose from the readymix concrete trucks in an attempt to enhance bond and reduce concrete water loss from the hot base surface.

Subsequent deflection indicated a weaken section in these areas during the initial pavement
life. Prewetting may be used sufficiently in advance of the paving machine to cool the asphalt surface. This distance should be long enough to allow the pavement to surface dry prior to the overlay application.

### 3.6 Direct Shear Testing

The primary objective of direct shear testing was to quantitatively measure the interface bond over time. A secondary objective of direct shear testing was to visually observe the interface bonding condition. Direct shear testing was added to the initial scope of field testing and was conducted when the project was 3 and 5 years old. Future testing is scheduled when the project will be 7 years old. Data presented herein represents testing conducted when the project was 3 and 5 years old.

### 3.6.1 Data Preparation

Data collected for each core obtained were assembled onto an Excel spreadsheet. Conditional observations related to bond condition when cores were obtained, acceptability of cores for testing, and break location were summarized numerically based on occurrence for each of the 8 sections tested. Data assembled on the Excel spreadsheet were copied into SPSS. Direct shear strength was identified as the dependent variable, and joint spacing, ACC surface preparation, and age were identified as factors. Levels within each factor were assigned dummy variables. Dummy variables assigned can be found on page 48.

### 3.6.2 Statistical Treatment and Results

The percent of cores visually observed to have a bonded interface when obtained in the field is shown in Figure 3.32. A high percent of cores were observed to be bonded when obtained in the field for both year 3 and 5, indicating that a bonded interface was normal
regardless of age or variables considered and that the coring method was nondestructive.

Figure 3.32 Percent of Cores Visually Observed to Have a Bonded Interface When Obtained in The Field

Figure 3.33 shows the percent of cores with bonded interfaces that were usable for testing. Cores considered usable for testing had at least 1 inch of sound ACC. In year 3, all sections except 52 and 62 had a high percent of cores that were usable for testing. In year 5, all sections except 62 had a high percent of cores that were usable for testing. This observation illustrates that the overall integrity of the ACC was good but variability with localized weak areas did exist. Additionally, the observations reaffirm that the methods used to obtain the cores were nondestructive.

Figure 3.33 Percent of Cores With Bonded Interfaces That Were Usable for Testing

To compare the effect of joint spacing and ACC surface preparation on direct shear strength, 2-way factorial analysis of variance with interaction was conducted. A significance level of 0.05 was used. Boxplots in conjunction with histograms were used to evaluate if the data were normally distributed. Examining the means for patterns of variance was used to evaluate whether the data exhibited equal variance. The data were found to satisfy the assumptions. The analysis was conducted by leaving missing data blank and by replacing missing data with factor level averages. A substantial difference was not observed when the 2 analyses were compared; therefore, results from leaving the missing data blank are discussed herein. Appendix E contains the ANOVA table for the 2-way factorial analysis of variance with interaction. Table 3.9 summarizes the results of the analysis. The results
indicate the following:

1. The model adequately explains the variance in the dependent variable
2. The factor of ACC surface preparation was significant

Table 3.9 Summary of Two-Way Factorial Analysis of Variance With Interaction for Direct Shear Strength

| Model | Significant <br> Factors | Model/Total Sum <br> Of Squares | Notes |
| :--- | :---: | :---: | :---: |
| JS/SP/AGE | SP | 0.491 | Interaction Was Significant |
| JS $=$ joint spacing | AGE $=$ age |  |  |
| SP = ACC surface preparation |  |  |  |

To compare direct shear strengths of different ACC surface preparations, a 1-way analysis of variance with post HOC tests was conducted. A significance level of 0.05 was used. Methods similar to those previously mentioned were used to evaluate whether the data were normally distributed and of equal variance. The data were found to satisfy the assumptions. Appendix E contains multiple comparison tables for the 1-way analysis of variance with post HOC tests. Table 3.10 details the results of the post HOC tests. The results indicate the milled surface preparation is significantly different from patch only and CIPR surface preparations.

Table 3.10 Summary of One-Way Analysis of Variance With Post HOC Test For Direct Shear Strength

| Factor | Significant Level | Compared To Level |
| :--- | :---: | :--- |
| SP | Milled | Patch Only, CIPR |

$\mathrm{SP}=\mathrm{ACC}$ surface preparation

Figure 3.34 depicts the percent of cores that were tested and broke at the interface or in the ACC. Cores considered to break at the interface had little to no ACC covering the PCC. Cores considered to break in the ACC had a thin layer of ACC completely covering the PCC. For both year 3 and 5, all sections except 10,11 , and 23 had a high percent of cores breaking in the ACC , indicating that the ACC is often weaker than the interface bond strength. Furthermore, sections 10, 11, and 23 have a milled surface preparation showing

Figure 3.34 Percent of Cores Tested That Broke at the Interface
that regardless of age a relationship between ACC surface preparation and break location exists. This relationship exists because sounder, cleaner ACC is created by milling off the top 0.25 inches of ACC that is oxidized, worn, brittle, and/or contaminated.

Figure 3.35 shows the average direct shear strengths for different break locations. For both years 3 and 5, greater direct shear strength was obtained with breaks at the interface
than within the ACC, reaffirming that the ACC is often weaker than the interface bond strength. This observation, coupled with the propensity for interface breaks, explains the superior performance of the milled surface preparation.

Figure 3.35 Average Direct Shear Strengths for Different Break Locations

### 3.7 Visual Distress Surveys

The primary objective of visual distress surveys was to monitor distresses in relation to the serviceability and bonding condition over time.

The visual distress surveys were conducted on a quarterly basis over the 5 years. Distresses were noted on each survey in terms of type, location, and number of effected slabs. The location of the distresses was identified by station, lane, and distance from edge of lane

Table 3.11 Visual Distress Summary (5 year)

or centerline. A summary of the accumulation of distress over the 5-year evaluation period is shown in Table 3.11. The test sections have been arranged in ascending order of overlay depth and joint spacing. The last group includes the 3 asphaltic concrete overlay sections that were compared as control section. The depth of asphaltic concrete overlay is the same one originally selected for the project. The information displayed in Table 3.11 is further discussed below in the same manner as presented in the table.

### 3.7.1 Two-Inch PCC Overlay

In general the cracking in the 2-inch overlay sections was minor in nature and limited to isolated areas in the tests sections. It was found in both directions of travel and limited to the outer wheel path of the roadway lane. Loss of the slabs was minimal and attributed to the cracking and the lack of paved shoulder to retain the slabs.

In the case of the 2-inch depth overlay depth, with 2-foot joint spacing, the predominate distresses that occurred were longitudinal, corner, and transverse cracking in descending order of magnitude. In total these distresses impacted less than $2 \%$ of the total test section slabs in this group. Performance was very good over the 5-year evaluation. The noted distresses were located primarily in the outer wheel path, in the outside 2 rows of slabs. The distresses began as longitudinal or corner cracking and over time evolved into fractured slabs. Such slabs remained in place and carried traffic until slabs in the outside edge row fractured and allowed the cracked slabs to move and dislocate. Fractured slabs represented only $0.2 \%$ of the test slabs and those dislocated or debonded slabs represented only $0.11 \%$ of the test slabs. The addition of fiber did appear to reduce the potential for longitudinal cracking and assist in the retention of slab integrity after cracking. Of the 3-base surface preparations, the broom and patch section exhibited the least amount of distress.

Changing the joint spacing to 4 feet and retaining the 2-inch overlay depth, increased the total amount of cracking to near $7 \%$ of the test slabs in the second group of sections. The predominate distresses continued to be longitudinal, corner and transverse cracking. As in the 2-foot squares, the location of the distress was concentrated in the outer wheel path or first row of slabs near the edge of the pavement. Changing the slab dimensions did increase the amount of the corner and transverse cracking levels and resulted in some $1.62 \%$ of cracked slabs that occurred in 1 section. The addition of fiber did assist in the retention of cracked slab integrity, but did not indicate a trend in the reduction of cracking. In this case the cold in place recycled base provided the location for the least amount of cracking.

### 3.7.2 Four-Inch PCC Overlay

Changing the depth of overlay to 4 inches resulted in a major decrease in the level of cracking. Distresses were again found primarily in the outer wheel path, in each direction of travel. Predominate distresses noted in the 4-inch overlay sections with 2-foot joint spacing were longitudinal and corner cracks as found in the 2-inch overlays. Cracking was limited to less than $0.1 \%$ of the test slabs. Distresses were located in the outer wheel path and along the longitudinal joint between row 1 and 2 from the pavement edge. Cracking was not reduced with the addition of fiber reinforcement. There were no instances of fractured slabs or debonding. The cold in place recycled base provided the lowest level of cracking and the milled surface exhibited minor cracking.

Increasing the joint spacing from 2 feet to 4 feet, in the 4 -inch overlay, decreased the total amount of cracking to less than $0.5 \%$ of the total slabs. In this case the transverse and longitudinal cracking were the primary distresses noted, at only minimal levels. The distresses were concentrated in 2 sections. The addition of fiber reinforcement appears to
have reduced the number of cracks in this case. Milling the base provided for the lowest level of cracking while brooming and patching accounted for the highest level of distress. No fractured slabs or evidence of debonding was noted over the test period in these sections.

The 4-inch overlay sections with 6-foot joint spacing exhibited primarily longitudinal and transverse cracking. The total amount of cracked slabs increased to less than $1.4 \%$ as compared to the other 4-inch slabs. Longitudinal cracking was the primary contributor in the distress and may be associated with joint formation timing and environmental conditions during construction. The addition of fiber reinforcement did not appear to have an impact of crack reduction. Milled base section provided for the lowest level of distress and the broom and patch sections provided for increased levels of cracking. No fractured slabs or evidence of debonding were noted over the test period in these test sections.

### 3.7.3 Six-Inch PCC Overlay

Less than $0.4 \%$ of the test slabs in the 6 -inch overlay depth with 6 -foot joint spacing exhibited any cracking or joint spalling. Longitudinal and transverse cracking accounted for the majority of distresses. The longitudinal distresses were located near the centerline and appear to be the result of improper joint formation timing. Fiber reinforcement appeared to have no impact on reduction in cracking levels. The cold in place recycled base provided for the least amount of cracking while milled surfaces provided a small amount of increase in the cracking levels. No fractured slabs or evidence of debonding were noted over the test period in these test sections.

Longitudinal, transverse, and corner cracking were the predominate signs of distress in the 6 -inch depth of overlay with 12 -foot transverse joint spacing. Less than $1.6 \%$ of the slabs in the test area exhibited cracking and it was confined to the areas parallel to the
centerline and a transverse crack at the midslab location. Levels of cracking were greater in the sections with fiber reinforcement. The type of base preparation made no difference in the amount or rate of cracking in this case and there were no fractured slabs encounter over the test period.

### 3.7.4 Eight-Inch PCC Overlay

In the case of the 8 -inch depth overlay sections, only 3 small sections were considered for the experiment. In this case some $11.0 \%$ of the slabs exhibited some type of visual distress in the form of longitudinal or transverse cracking. The majority of the cracking was found in the longitudinal cracks adjacent to the centerline. Visual inspection leads the research team to believe that the crack formed before the centerline joint was cut. Removal of the cement treated base in section 1 caused the pavement replacement to exhibit increased levels of cracking over section 30. In the case of the centerline longitudinal cracks in sections 30 and 31, joint development timing is the primary source of distress.

### 3.7.5 Asphaltic Concrete Overlay Sections

The asphaltic concrete overlay sections, built to a depth of 4.5 inches also exhibited distress over the 5-year test period. Transverse cracks, spaced evenly, and in the form of thermal cracks appeared in the middle of the test period during the same winter that the cracks began to appear in the portland cement concrete sections. The level of cracking was independent of the base preparation and consisted primarily of full pavement width cracks with an occasional lane width transverse crack or diagonal cracks. These cracks have remained open during the remainder of the test period, even though the maintenance staff has filled them once with liquid joint filler. The edges of the cracks are beginning to show signs
of folding down into the cracks and secondary cracks are being formed parallel to the original cracks.

### 3.7.6 Portland Cement Concrete Overlay Sections

Areas of high distress in which debonding had occurred, was suspected, or was probable were targeted for additional investigation with aforementioned testing.

### 3.7.7 Data Preparation

Distress data were assembled into an Excel spreadsheet. Sections exhibiting a high amount of cracking and fractured slabs were identified. Distress locations were reviewed to determine specific areas of interest within the identified sections. FWD deflection responses and field observations from distressed and normal areas were assembled into an Excel spreadsheet for comparison. Comparisons of the deflection responses focused on deflection basin shapes and percent decrease in percent reduction in deflection over time. Comparisons of the field observation focused on material soundness and bond condition of cores obtained.

### 3.7.8 Special Statistical Treatment and Results (Sections 23 and 62)

Sections 23 and 62 were identified as exhibiting a high amount of cracking and fractured slabs. Table 3 details the cumulative occurrence of distresses from 11/95 to 12/97 for sections 23 and 62. These sections were the only sections exhibiting several fractured slabs in this time period. The fractured slabs were clustered together in 1 or 2 groupings, indicating the behavior was localized and was initiated by a unique set of circumstances. A limited amount of data was collected because distress development occurred near the end of the 3-year scope of this research and in a small number of areas. Graphical and visual comparisons were used to evaluate the data.

The deflection basins resulting from normal and fractured slab locations for section 23 and 62 are shown in Figure 3.36 and Figure 3.37 respectively. The deflection basins for section 23, year 3, fractured and normal slabs are almost identical. This observation is unexplained considering the substantial amount of distress observed in the tested area. The deflection basins for section 62, year 3, fractured and normal slabs are substantially different. Year 3 fractured has a greater magnitude for every radial distance and appears more bow shaped. These characteristics create a distinct similarity to pre-UTW, indicating bonding and structural integrity was compromised.

Several cores were obtained from normal and fractured slab locations of section 23 and 62. Cores from the fractured locations of section 23 showed dirt contamination at the interface with little to no bonding. Cores from the fractured locations of section 62 had completely rubblized ACC with no bonding. Cores from the normal areas of these sections had no contamination or rubblized ACC, indicating that the debonding and distresses resulted from a unique set of circumstances not characteristic of the whole section. The circumstances are believed to have occurred due to construction problems. In section 23, dirt contamination is believed to have occurred as a result of trucks driving on the prepared ACC surface with muddy tires. In section 62 , rubblized ACC is believed to have occurred as a result of heavily loaded trucks driving on the CIPR prior to adequate curing.

## 4. SUMMARY

### 4.1 Introduction

The objective of the research project as noted in the contract with the Iowa DOT and FHWA was the evaluation of bond development and retention between the portland cement concrete overlay and the underlying asphaltic concrete base material. The evaluation was to be done in relationship to various base surface preparation methods, overlay depths, and jointing patterns. The project also allows for the indirect evaluation of sealed versus unsealed joints in the overlay and the impact of the addition of fiber reinforcement to the overlay material in effort to limit distresses.

The research staff chose to evaluate the bonding between layers in many ways. The primary methods employed included:

1. Direct shear testing and visual observations of cores from the pavement.
2. Deflection testing to determine modulus values for each of the pavement layers assuming bonded or unbonded conditions, and load transfer between slabs.
3. Horizontal and vertical strain at the corners of selected slabs with sensors positioned at the interface of portland cement concrete and asphaltic concrete.
4. Visual surface distress type and magnitude that are associated with bonded and unbonded overlays.

### 4.2 Bond Evaluation Conclusions

1. Bonding of the overlay to the asphaltic concrete was achieved in all sections at construction through conventional paving methods.
a. Direct shear tests throughout the project duration indicated the failure plane to
be located approximately 1 inch into the asphaltic concrete.
b. Deflection measurements taken in the field matched those associated with theoretical values assuming full bonding of layers.
c. No visual distresses associated with the lack of bond were noted immediately after construction.
d. Interface strain measurements were inconclusive, but did tend to be reduced as the overlay cured, indicating the development of bond and the interaction of materials.
2. Bond strength varied with base surface preparation methods.
a. Direct shear test indicate the highest shear strengths on milled base surfaces, average shear values on broomed surfaces and lowest values for shear strength on the cold in place recycled surfaces.
b. Direct shear tests indicate that the bond relationship with surface preparation is retained over the evaluation period of 5 years.
c. Prewetting of the base at the paving machine produced a negative impact on bond strength development.
3. Deflection testing over the evaluation period indicated that traffic loadings and environmental conditions did contribute to increasing deflections over time that indicate a loss of composite action in the cross section. Deflection increases may be the result of the overlay debonding, asphalt layers delaminating, or both.
4. Visual cracking increased over time in isolated areas of the outer wheel path in the 2 -inch depth of overlay sections.
a. Distress development rates accelerated at times of severe freeze-thaw cycling
and periods of high moisture and air temperature combinations.
5. Structural integrity and bond was retained on $99.9 \%$ of all slabs in the 2 and 4 inch, ultrathin overlay sections, over the 5 years.
6. Bond can be restored in individual sections through the use of epoxy injection repair methods.

### 4.3 General Project Conclusions

The following conclusions are drawn from the distress survey information and relate the variables of base surface preparation, overlay depth, and joint pattern sizes.

### 4.3.1 Base Surface Preparation

1. Milling of the base surface provides an excellent bonding surface, longitudinal and transverse profile and overlay depth control surface.
2. Broom and patch base surfaces provide adequate bonding if kept clean of dirt and debris, but requires more quality and quantity control to meet overlay depth requirements.
3. Cold-in-place recycled base surfaces provide the lowest bond strengths. They must be adequately cured prior to the concrete placement to retain stability. This method provides good concrete overlay depth control.

### 4.3.2 Concrete Overlay Depth

1. Two-inch depth concrete overlays do perform well in excess of 5 years when placed with good depth control at construction.
2. Two-inch depth concrete overlays exhibit surface distresses in the form of longitudinal or corner cracks leading to fractured slabs and debonding.
3. Two-inch depth concrete overlay distress occurs primarily in the outside wheel path (4 feet) areas.
4. Fiber reinforcement can add durability and life to the 2-inch depth overlays in terms of holding cracks together.
5. Four-inch depth concrete overlays performed well over the 5-year evaluation period with minimal visual distress.
6. Distress in the 4-inch depth concrete overlay sections was limited to longitudinal, transverse and corner cracking in the outer wheel path (4 foot) of each lane.
7. No debonding was associated with the 4-inch depth concrete overlay sections.
8. The benefits of adding fiber reinforcement in the 4 -inch depth concrete overlays were not conclusive.
9. The 6 -inch depth concrete overlays performed well as expected with only occasional longitudinal and transverse cracking noted.
10. Cracking in the 6 inch depth concrete overlay sections was primarily associated with longitudinal and transverse joint development construction practices.
11. Fiber reinforcement impacts on the 6-inch depth concrete overlay sections were inconclusive.
12. No debonding was associated with the 6 -inch depth concrete overlay sections.
13. Eight inch depth concrete overlay sections exhibited only minimal cracking that was associated with construction practices, such as base removal or late joint development.

### 4.3.3 Longitudinal and Transverse Joint Patterns

1. The use of 2-foot by 2 -foot joints in the 2-inch depth concrete overlays places a
longitudinal joint in the wheel path and can provide a line of weakness and distresses.
2. Application of the 2-foot by 2 -foot joints with the 4 -inch depth concrete overlays eliminated the longitudinal joint, wheel path distress problem.
3. Cracking rates were greatly increased when 4 -foot by 4 -foot joints were employed with 2-inch depth concrete overlays.
4. The use of 4-foot by 4-foot or 6-foot by 6 -foot joint patterns with 4 -inch depth concrete overlays provided very good performance in terms of minimizing distress.
5. Application of 6-foot by 6 -foot joint patterns provided improved cracking performance over the 6 -foot by 12 -foot joint pattern, when used with the 6 -inch depth concrete overlays.

### 4.3.4 Joint Preparation

1. The performance of narrow, unsealed joints (longitudinal and transverse) was successful over the 5-year evaluation period with no signs of raveling or joint spalling of any magnitude being identified.

Based on the information gained from this research, the research team believes that the optimum conditions that promote good performance in an ultrathin concrete overlay are milling of the existing base surface, leaving a minimum of 3 to 4 inches of sound asphaltic concrete base, existing asphalt surface milling, overlay depths of a minimum of 3 to 4 inches with good construction grade and depth control, the addition fibers in 3-inch depths, 4 to 6 -foot joint spacings, and the use of early cut narrow joints with no sealant.

### 4.4 Future Research Needs

1. Evaluation of rehabilitation methods for ultrathin pavements using portland cement concrete patching materials and methods.
2. Extended evaluation of this project to gage ultrathin life expectancy in excess of 5 years.
3. Consideration of the use of ultrathin depths of overlay and joint patterns for use on existing composite pavements.

APPENDIX A. CONSTRUCTION INSPECTION AND TESTING RESULTS

## APPENDIX B. STRAIN AND TEMPERATURE STATISTICAL ANALYSIS

Plots of average strain $A B$ and $C D$ versus $P C C$ thickness

PCC Thickness (3, 5, 7 in.)

Plots of average strain AB and CD versus joint spacing

Plots of average strain AB and CD versus ACC surface preparation

Plots of average strain AB and CD versus synthetic fiber usage

Plots of average strain AB and CD versus temperature

Plots of average strain AB and CD versus age

Age (days)

Age (days)

Two-way factorial analysis of variance with interaction for transformed average strain AB and CD by PCC thickness (T), joint spacing (JS) with temperature (Temp) and age (AGE)

ANOVA ${ }^{\text {a,b,c }}$

|  |  |  | Unique Method |  |  |  |  |

## APPENDIX C. FALLING WEIGHT DEFLECTOMETER PERCENT REDUCTION IN DEFLECTION RESPONSES STATISTICAL ANALYSIS

Plots of percent reduction in deflection responses D0, D1, D2, and D3 versus PCC thickness

PCC Thickness (3, 5, 7 in.)

PCC Thickness (3, 5, 7 in.)

PCC Thickness (3, 5, 7 in.)

PCC Thickness (3, 5, 7 in.)

Plots of percent reduction in deflection responses D0, D1, D2, and D3 versus joint spacing

Plots of percent reduction in deflection responses D0, D1, D2, and D3 versus ACC surface preparation

Plots of percent reduction in deflection responses D0, D1, D2, and D3 versus synthetic fiber usage

Synthetic Fiber Usage (no fiber, fiber)

Two-way factorial analysis of variance with interaction for percent reduction in deflection responses D0, D1, D2, and D3 by PCC thickness (T) and joint spacing (JS)

## APPENDIX D. FALLING WEIGHT DEFLECTOMETER CHANGE IN PERCENT REDUCTION IN DEFLECTION RESPONSES STATISTICAL ANALYSIS

Plots of change in percent reduction in deflection responses D0, D1, D2, and D3 versus PCC thickness

PCC Thickness (3, 5, 7 in.)

PCC Thickness (3, 5, 7 in.)

PCC Thickness (3, 5, 7 in.)

PCC Thickness (3, 5, 7 in.)

Plots of change in percent reduction in deflection responses D0, D1, D2, and D3 versus joint spacing

Plots of change in percent reduction in deflection responses D0, D1, D2, and D3 versus ACC surface preparation

Plots of change in percent reduction in deflection responses D0, D1, D2, and D3 versus synthetic fiber usage

Plots of change in percent reduction in deflection responses D0, D1, D2, and D3 versus age

Two-way factorial analysis of variance with interaction for change in percent reduction in deflection responses D0, D1, D2, and D3 by PCC thickness (T), joint spacing (JS) with age (AGE)
